Ákos Kádár

geboren op 30 december 1989 te Budapest, Hungary

Promotores

Prof. Dr. E. Postma

Dr. A. Alishahi

Commissieleden

Prof. Dr. A. Gatt

Prof. Dr. A. van den Bosch

Dr. C. Gardent

Dr. F. Schilder

Dr. M.B. Goudbeek

*“My principal motive is the belief that we can still make admirable sense of our lives even if we cease to have ...
an ambition of transcendence”*

– Richard Rorty

“Outside is pure energy and colorless substance. All of the rest happens through the mechanism of our senses. Our eyes see just a small fraction of the light in the world. It is a trick to make a colored world, which does not exist outside of human beings.”

– Albert Hoffman

No book can ever be finished. While working on it we learn just enough to find it immature the moment we turn away from it.”

– Karl Popper

Acknowledgements

I would like to thank my main supervisor Afra Alishahi for providing the PhD opportunity and NWO for the funding. Thanks also go to my second supervisor Grzegorz Chrupała for joining the project and putting effort into improving the thesis. They started me off on my path as a researcher and will have a lasting impact on my future development. Eric Postma, my promotor, oversaw the process and gave crucial input especially at the finishing stages for which I'm grateful. Thank goes to the Integrating Vision and Language COST Action unit for providing me with the "Short Term Scientific Mission grant" and for Tartu University for hosting. Tambet Matiisen was an exceptional host and I hope that we have an entangled future ahead of us. Further thanks go to the organizers of the "Integrating Vision and Language Summer School" for awarding me the trainee grant twice in a row and the same goes to the organizers of the "LxMLS Summer School". I had a wonderful time working for Microsoft Research Montreal during my five months internship and I am very grateful for the opportunity and for the mentorship my colleagues provided. I would also like to thank my collaborators Desmond Elliot and Marc-Alexandre Côté for their contributions to my thesis. It was such a pleasure working together and I hope we will have the opportunity to continue in the future despite the current dystopia created around "intellectual property rights". The future's uncertain and the end is always near. Let it roll, baby, roll!

Introduction

The ability to understand natural language plays a central role in humans' conception of intelligent machines. Alan Turing already in his now famous Imitation Game (Turing, 1950) gives natural language understanding a key role in tricking humans into thinking that they are interacting with their fellow specimen rather than a machine. One of the goals of Natural Language Processing (NLP) is to develop algorithms and build systems to help machines understand what humans are talking about; to understand the *meaning* of natural language utterances.

In the first part of the thesis I explore computational techniques to **learn the meaning of words and sentences** considering the **visual world** as a naturally occurring **meaning representation**. Furthermore, I consider images as a means to **bridge** between languages and presented methods seeking to find relationships between

images and natural utterances in multiple languages.

The Chapters of the thesis follow a progression starting with a single language at the word-level and arriving to multilingual visually grounded sentence representations:

Chapter 1 introduces the topic and contributions of the thesis.

Chapter 2 discusses the related work and technical background in detail.

Chapter 3 presents a cognitive model of language learning that learns *visually grounded word representations*.

Chapter ?? focuses on *visually grounded sentence representations* and their interpretations from a linguistic perspective using the architecture that is the basis for the chapters to follow: combination of a Convolutional Neural Network to extract visual features and a Recurrent Neural Network to learn sentence embeddings.

Chapter 5 applies visually grounded representation learning approach that forms the basis of Chapter ?? to *improve machine translation* in the domain of visually descriptive language.

Chapter 6 shows the clear benefits of learning visually grounded representations for multiple languages jointly.

Chapter ?? extends the investigations of Chapter 6 to the cross-domain setup, breaking the assumption that for each language the same images are annotated with different languages.

Learning representations

The foundational methodology applied in all chapters is *statistical learning*. The early days of NLP were characterized by rule-based systems building on such foundations as Chomskyan theories of grammar (Chomsky, 1957) or Montague Semantics (Montague, 1970). Since the 1980s partly due to such theories falling out of fashion, but also due to the increase in the amount of available computational power Machine Learning (ML) approaches revolutionized the field. **Learning** in general proved to be a crucial component to Artificial Intelligence and also specifically in NLP. Machine Learning algorithms are designed with the goal that given an increasing number of examples a system improves its performance according to some measure of success. Reflecting the structure of ML itself and the popularity of ML within the field, NLP research follows a task-oriented methodology: researchers borrow or collect data sets, define measures of success and develop or apply learning algorithms. Chapters 5, 6 and ?? closely follow this blueprint.

From the rule based times of "engineering grammars" researchers moved onto "engineering features" to **represent** the textual data as input to general-purpose pattern recognition algorithms such as decision trees, support-vector machines or conditional random fields.. A large set of these feature templates are still based on various formal-linguistic theories requiring various linguistic taggers and parsers to assign structure to raw texts. Intuitively, different applications such as machine translation or goal-oriented dialogue systems require different input representations. Furthermore, one would assume that various languages require different feature-extraction pipelines reflecting the typological differences across languages.

Linguistic representation learning challenges this intuition and is interested in discovering general principles that allows machines to learn linguistic representations from *raw data*, which are more or less generally applicable. This line of work, as well as the approaches presented in the thesis, fit in the general **representation learning** framework consisting of machine learning approaches that learn useful representations for various tasks from (close to) raw input.

The expression "representation learning" is somewhat synonymous with "deep learning" at the time of writing this thesis (Bengio et al., 2013a). When mentioning representation learning in the deep learning context it is usually meant that the goal is to learn a function from raw input to target labels. In the context of this thesis, however, the emphasis is on learning representations of words, phrases and sentences that are potentially *generally useful*, meaning that they can be used as input to many tasks. This is sometimes referred to as *transfer learning* (Pratt, 1993) where we seek to identify unsupervised learning objectives, supervised tasks, self-supervision schemes or the combinations of these to learn representations that perform well on a large variety of problems.

Learning representations of words

Most attempts to build general representations for words are based on the *distributional hypothesis* of word meaning. It states that the degree to which words are similar is a function of the similarity of the linguistic context they appear in. In other words, similar words appear in similar contexts. Computational models of distributional semantics implement this intuition and learn real-valued word vectors based on co-occurrence statistics in large text corpora. To aid the reader

with technical and historical context we introduce distributional semantics models using the *count-based/prediction-based* distinction borrowed from Baroni et al. (2014b). Section 2.1.1 introduces earlier *count-based* methods building word-context co-occurrence vectorspace, while Section 2.1.2 presents the *prediction-based* framework in a more detailed fashion as the techniques discussed here are closely related to the approaches presented in this thesis. Section 2.1.2 details efficient linear models for predictive word-learning for two main reasons: 1.) linear word-learning methods had a tremendous impact on shaping the current landscape of continuous linguistic representation learning and are still widely used at the time of writing this thesis, 2.) our main point of comparison for our word learning model in Chapter 3 is one of such models detailed in the section.

Word-representations within the prediction-based framework are an instance of *representation learning*: word representations – usually referred to as *word embeddings* – are learned through optimizing model parameters to predict context from words or words from context. Such learned word-representations have proven successful in many applications especially in recent years, however, they are not *realistic* in a certain sense. While they capture many aspects of syntax and semantics of natural language they bare no relationship to the language external world. This leads us to the main topic of the thesis: *visual grounding* introduced in the following section.

Visually grounded word representations

Many theories of human cognition supported by empirical evidence state that human language and concept representation and acquisition is *grounded* in perceptual and sensori-motor experiences. Cross-

situational word learning, an influential cognitive account of human word learning, supposes that humans learn the meanings of words exploiting repeated exposure to linguistic contexts paired with perceptual reality. Learning representations for linguistic units in a visually grounded manner brings computational language learning systems closer to human-like learning. Such theoretical considerations are detailed in Section 2.2.1.

The applicability of distributional language representations in the larger scope of Artificial Intelligence. One of the dreams of AI is to develop technology to power intelligent embodied agents taking the form of office assistants or emergency aid robots. These machines cannot implement natural language as an arbitrary symbol manipulation system akin to a calculator’s understanding of magnitudes or slopes. Similarly to humans they need to link linguistic knowledge to the extra-linguistic world.

Furthermore, certain aspects of meaning are better captured by *encyclopedic* knowledge is abundant in textual data, however, *perceptual* information can provide complementary valuable insights into physical properties rarely mentioned in texts such as *size*, *shape* and *color*. In practice harnessing the visual modality to learn language representations that link linguistic knowledge to the external world has been empirically shown to improve performance on several semantic tasks as detailed in Section 2.2.2.

In terms of computational modeling the jump from distributional to grounded models is conceptually simple: one needs to collect data where the *contexts* of linguistic units are *extra-linguistic* and represent these contexts such that they can be provided as input to representation learning algorithms. More concretely in terms of extra-linguistic

context the present thesis focuses on the *visual modality*.

Linguistic-visual multi-modal representations on the word level have a well established albeit somewhat brief history (Section 2.2.2). Such methods were developed both within the *count-based* and *prediction-based* frameworks using computer vision techniques to represent the *visual modality* and NLP methods to represent texts. These separate spaces are then combined into a single multi-modal representation.

As the **first contribution** of the thesis in Chapter 3 we present an incremental cross-situational model of word learning introducing modern computer-vision techniques to computational cross-situational modeling of human language learning. Through our experiments we show that our presented model is competitive with state-of-the-art *prediction-based* distributional models and that our model can name relevant concepts given images.

Visually grounded sentence representations

When moving from *atomic* words to the *compositional* world of sentences we need flexible models that can represent word-order and hierarchical relationships. In Chapters 4, 5 6 and ?? we use Recurrent Neural Networks, which form a powerful class of sequence models to represent sentences. Section 2.3 provides the reader with historical and technical background to the considerations behind this choice.

The study of general sentence representation learning has a much briefer history than word-representations and Section 2.4 situates the reader in the area. Most approaches to learn useful sentence representations to date are based also on the distributional hypothesis and formulate general purpose representation learning as a sort of linguistic context prediction, but on the sentence level.

Section 2.5 describes the general framework of learning visually-grounded sentence representations and their utility. The basic idea is still context prediction, however, we learn associations between sentences and their *visual* context i.e model parameters are optimized such that related image sentence pairs get pushed close together and unrelated pairs far from each other in a learned joint space.

As the **second contribution** of this thesis in Chapter 4 we train such an architecture and explore the learned representations. Our main interest and contribution here is the development of general techniques to *interpret* linguistic representations learned by Recurrent Neural Networks and use these techniques to contrast text-only language models with their grounded counter parts trained on the same sentences.

Visual modality bridging between languages

One of the intriguing aspects of using the visual modality as a naturally occurring meaning representation is that it is also naturally *universal* across languages. The visual modality anchors linguistic representations to perceptual reality, but also provides a natural bridge between various languages. Linguistic utterances that are similar to each other, intuitively, appear in the context of perceptually similar scenes across languages.

Utterances in multiple languages and corresponding perceptual stimuli can be conceptualized as *multiple views* of the same underlying abstract object. Learning to map these multiple views to the same feature space can lead to better representations as they have to be more *general* due to the model having to solve multiple tasks at the same time. This *multi-view learning* perspective is explained in more

detail in Section 2.6.1 focusing on the specific case of multi-modal and multi-lingual representations we explore in Chapter 6 and ??.

The visual modality as pivot on the word-level can be used to find possible translations for words when no dictionary is available. Section 2.6.2 provides the reader with more detail on bilingual lexicon induction using the visual modality. Extending this idea from word to sentence level gives rise to techniques that use the visual modality as a pivot to translate full sentences. Approaches in this direction are discussed in Section 2.6.3.

The **third contribution** in the thesis combines visually grounded sentence representation learning with machine translation. More specifically in Chapter 5 we present a *multi-task* learning architecture that jointly learns to associate English sentences with images and to translate from English to German. We show that visually grounded learning improves translation quality in our domain and that it provides orthogonal improvements to having a large additional English-German parallel corpus.

The **fourth contribution** of this thesis is exploring visually grounded sentence representations learned for multiple languages jointly. In Chapter 6 we show that better grounded representations can be learned by training on multiple languages. We find a consistent pattern of improvement whereby multilingual visually grounded sentence representations outperform bilingual ones, which outperform mono-lingual representations. Furthermore, we provide empirical evidence that the quality of visually grounded sentence embeddings on lower-resource languages can be improved by jointly training together with data sets from higher-resource languages.

Lastly, our **fifth contribution** in Chapter ?? is exploring the

benefit of multilinguality in visually grounded representation learning as in Chapter 6, but in the cross-domain setting. Here we consider a *disjoint* scenario where the image sentence data sets for different languages do not share images. We assess how the method applied in Chapter 6 performs under domain-shift. Furthermore, we introduce a technique we call *pseudopairs*, whereby we generate new image–caption data sets by creating pairs across data sets using the sentence similarities under the learned representations. We find that even though this technique does not require any additional external data source, models or other pipeline elements, it consistently improves image sentence ranking performance.

2

Background

Distributed word-representations

The distributional approach to word meaning hypothesizes that semantically related words tend to appear in similar contexts. This idea goes back in linguistics tradition to the earlier days of American structuralism (Nevin & Johnson, 2002). As early as in 1954 in his seminal paper "Distributional structure" Harris claims that distribution should be taken as an explanation for word meaning and that similarity classes can be constructed based on co-occurrence statistics (Harris, 1954). Cruse & Cruse (1986) writes that "It is assumed that the semantic properties of a lexical item are fully reflected in the appropriate aspects of the relations it contracts with actual and potential contexts" and that "the meaning of a word is constituted by its contextual relations". Computational models of distributional

semantics implement this intuition and learn real-valued word vectors based on co-occurrence statistics in large text corpora. Here we present such representations using the *count-based–prediction-based* distinction borrowed from Baroni et al. (2014b).

Count-based approaches

Early computational linguistics models of distributional semantics fall in the category of count-based approaches: they store counts of the number of times target words appear in different contexts. In the resulting co-occurrence matrix \mathbf{W} each row \mathbf{W}_i represents a word i and each column $\mathbf{W}_{,j}$ a context. It has size is a $\mathbf{W} \in \mathbb{N}^{|V| \times |C|}$ where V is the set of words and C is the set of contexts. The entry $\mathbf{W}_{i,j}$ is the number of times word i appears in context j . Contexts are typically words appearing within a certain window size or text documents. To the counts in W various re-weighting schemes are applied followed by some matrix factorization algorithm resulting in a lower dimensional dense representation $\mathbf{W} \in \mathbb{R}^{|V| \times d}$, where $d < |C|$.

The earliest approaches include Hyperspace Analogue to Language (Lund & Burgess, 1996), which constructs a term-term co-occurrence matrix and Latent Semantic Analysis (Dumais, 2004), which applies the tf-idf re-weighting scheme on a term-document matrix followed by singular-value decomposition. More recent approaches apply different re-weighting schemes such as point wise mutual information Bullinaria & Levy (2007) and local mutual information (Evert, 2005) or different matrix factorization algorithms such as non-negative matrix factorization (Baroni et al., 2014b).*

*For a comprehensive set of empirical experiments on count-based approaches please consult Bullinaria & Levy (2007) and Bullinaria & Levy (2012).

Prediction-based approaches

In more recent years various deep learning methods have been applied to learn distributed word-representations usually referred to as *word-embeddings* in the literature. Contrary to count-based methods prediction-based approaches fit into the standard machine learning pipeline: they optimize a set of parameters to maximize the probability of words given contexts or contexts given words, where the word-embeddings \mathbf{W} themselves form a subset of the parameters of the full model.

Neural language models

Laying down the framework for recent developments the first modern approach to learn distributed word-representations from realistic data was the neural language model introduced by Bengio et al. (2003). They present a feed-forward multilayer perceptron with continuous word-embeddings, a single hidden layer and a softmax output layer. More precisely the model is parametrized by a 1.) word-embedding matrix $\mathbf{W} \in \mathbb{R}^{|V| \times d}$, where each row corresponds to a word-vector \mathbf{W}_i of size d and each column \mathbf{W}_j to a learned feature, 2.) hidden and output weight-matrices \mathbf{H} and \mathbf{U} . Similarly to the case of count-based embeddings $d < |V|$. The network takes as input the concatenation of n word-vectors preceding the target word as context representation $\hat{\mathbf{w}} = [\mathbf{w}_1; \dots; \mathbf{w}_{n-1}]$ and outputs the probability distribution over the current word w_n . The computation of the network is shown in Equation 2.1:

$$P(w_n | w_{<n}) \approx \text{softmax}(\mathbf{U} \tanh(\mathbf{H} \hat{\mathbf{w}} + b_h) + b_u) \quad (2.1)$$

where \tanh is the hyperbolic tangent function applied elementwise

$$\tanh(x) = \frac{e^{2x} - 1}{e^{2x} + 1} \quad (2.2)$$

and softmax is a commonly used function to map a vector of unnormalized scores to a categorical probability distribution:

$$\text{softmax}(x) = \frac{e^{x_i}}{\sum_{k=1} e^{x_k}} \quad (2.3)$$

The model is trained to maximize the probability of the target word given the previous fixed number of words as context over a training corpus – n -gram language model – trained with stochastic gradient descent (Cauchy, 1847) through the backpropagation algorithm (Rumelhart et al., 1985). The superior performance of the feed-forward neural language model has soon been shown to improve performance in speech recognition (Schwenk & Gauvain, 2005).

Following a similar recipe the convolutional architecture of Collobert & Weston (2008) based on the time-delay neural network model (Waibel et al., 1990) took several steps towards the by now standard practices in deep NLP. Contrary to the feed-forward network the convolution over-time structure can handle sequences of variable length. This is essential for NLP applications where typically sentences are composed from a varying number of words. They introduces the idea of jointly learning many linguistic tasks at the same time such as part-of-speech tagging, chunking, named entity recognition and semantic role labeling through *multi-task learning*. Their architecture was later refined in Collobert et al. (2011) and the pre-trained full model was made available alongside the stan-

dalone word-embeddings in the SENNA toolkit.[†] Finally, Collobert & Weston (2008) were the first to show the utility of pre-trained word-embeddings in other tasks through transfer learning.

We also make extensive use of the multi-task learning strategy: Chapters 4 for a language modeling and image–sentence ranking, in Chapter 5 for machine translation and image–sentence ranking and in Chapters 6 and ?? for image–sentence and sentence–sentence ranking in multiple languages.

The architecture, however, that arguably became most popular in NLP – which we also use in Chapters 4, 5, 6 and ?? – is the recurrent neural network (RNN). It was first introduced by the late Jeffrey L. Elman in his seminal paper ’Finding Structure in Time’ as a model of human language learning and processing (Elman, 1990). Recurrent neural networks take a variable length sequence as input and perform a stateful computation over it’s elements. essentially ”reading” the input from left-to-right. In case of language modeling at each time-step t the network takes an input word vector \mathbf{w}_t and the it’s previous hidden state \mathbf{h}_{t-1} maintained through previous time-steps. These are used to compute the current state \mathbf{h}_t and to predict the probability distribution over the following word $P(w_t|w_{<t})$. It is parametrized by a word-embedding matrix $\mathbf{W} \in \mathbb{R}^{|V| \times d}$, an input to hidden weight matrix \mathbf{W}_i , a hidden to hidden weight matrix \mathbf{W}_h and finally the hidden to output weight matrix \mathbf{U} to predict the unnormalized probabilities over the vocabulary entries:

[†]<https://ronan.collobert.com/senna/>

$$P(w_n | w_{n < n}) \approx \text{softmax}(\mathbf{U}\mathbf{h}_t + \mathbf{b}_o) \quad (2.4)$$

$$\mathbf{h}_t = \tanh(\mathbf{W}_h \mathbf{h}_{t-1} + \mathbf{W}_i \mathbf{w}_t + \mathbf{b}_h) \quad (2.5)$$

where \mathbf{b}_o and \mathbf{b}_h are bias terms.

This model is also trained to maximize the probability of the training sequences, but rather than standard backpropagation it is optimized with the backpropagation through time algorithm (BPTT) (Robinson & Fallside, 1987; Werbos, 1988; Williams & Zipser, 1995) developed for RNNs.

Elman (1991) shows when trained on simple natural language like input the hidden states of the network \mathbf{h}_t encode grammatical relations and hierarchical constituent structure. In Chapter 4 we also train a recurrent language model and compare it to its grounded counterpart on real-world data and explore similar questions about the learned opaque representations as Elman (1991).

Despite the early successes, however, it turned out to be difficult to train Elman networks on practical applications with longer sequences due to the vanishing and exploding gradient phenomena (Bengio et al., 1994). It wasn't until the RNNLM implementation of Mikolov et al. (2010)[‡] established a new state-of-the-art on language modeling that RNNs regained their popularity in language processing. Interestingly the successful application the standard BPTT algorithm to simple RNNs on real world language modeling Mikolov (2012) seems only to have required more computational resources and the now widely used gradient clipping trick. Still at the time

[‡]<http://www.fit.vutbr.cz/~imikolov/rnnlm/>

of writing this thesis RNNs are trained with BPTT with various versions of stochastic gradient decent and smart initialization strategies, while more complex training algorithms such as hessian-free optimizers (Martens & Sutskever, 2011) remain out of fashion.

At the time of writing this thesis an overwhelming amount of empirical evidence shows that new RNN variants the long short-term memory (LSTM) (Hochreiter & Schmidhuber, 1997; Gers et al., 1999) and gated recurrent unit networks (GRU) (Cho et al., 2014b) vastly outperform the simple Elman network in practice. We use GRUs in Chapters 4, 5, 6 and ??.

Gated recurrent unit networks use a particular *memory structure*, which adds an inductive bias to the network to make it easier to learn to *carry information* over time by keeping a portion of the components of the hidden state \mathbf{h}_t approximately constant at each step:

$$\begin{aligned} \mathbf{z}_t &= \sigma(\mathbf{W}_z \mathbf{w}_t + \mathbf{U}_z \mathbf{h}_{t-1} + \mathbf{b}_z) && \text{(update-gate)} \\ \mathbf{r}_t &= \sigma(\mathbf{W}_r \mathbf{w}_t + \mathbf{U}_r \mathbf{h}_{t-1} + \mathbf{b}_r) && \text{(reset-gate)} \\ \tilde{\mathbf{h}}_t &= \tanh(\mathbf{W}_h \mathbf{w}_t + \mathbf{r}_t \odot \mathbf{U}_h \mathbf{h}_{t-1}) && \text{(memory content)} \\ \mathbf{h}_t &= (1 - \mathbf{z}_t) \odot \mathbf{h}_{t-1} \mathbf{z}_t \odot \tilde{\mathbf{h}}_t && \text{(hidden state)} \end{aligned}$$

where σ is the sigmoid function:

$$\sigma(x) = \frac{e^x}{e^x + 1} \quad (2.6)$$

As the sigmoid function has a range of $[0, 1]$ it is intuitive to understand the GRU as a sort of sequential computer with soft/continuous read-write memory operations: the reset-gate \mathbf{r}_t decides how much

of each component of the previous state is relevant to be mixed in with the current input, resulting in the current candidate memory state $\tilde{\mathbf{h}_t}$. The output-gate then trades off the previous state with the current candidate.

Efficient linear models

Despite the success of deep learning architectures in NLP it wasn't until the introduction of the much simpler and fast continuous bag-of-words and skip-gram with negative sampling (SGNS) algorithms Mikolov et al. (2013a) packaged into the easy to use `word2vec` toolkit[§] that word-embeddings became ubiquitous in computational linguistics and NLP research. These algorithms rely on simple log-linear models as opposed to the more expensive neural networks leading to faster training on larger corpora. The more successful SGNS model has two learnable word embeddings matrices one for the target words $\mathbf{W}_w \in \mathbb{R}^{|V| \times d}$ and a separate one for the contexts $\mathbf{W}_c \in \mathbb{R}^{|V| \times d}$. The model is trained to maximize the dot product $\mathbf{c}^T \mathbf{w}$ between true word-context pairs (w, c) appearing in corpus and minimize the dot product $\hat{\mathbf{c}}^T \mathbf{w}$ between randomly samples contrastive examples (w, \hat{c}) through maximizing the following loss function

$$J(\theta) = \prod_{(w,c) \in D} p(D = 1 | w, c; \theta) \prod_{(w,c) \in D'} p(D = 0 | w, c; \theta) \quad (2.7)$$

$$= \sum_{(w,c) \in D} \log \sigma(\mathbf{c}^T \mathbf{w}) \sum_{(w,c) \in D'} \log \sigma(-\mathbf{c}^T \mathbf{w}) \quad (2.8)$$

where $p(D = 1 | w, c)$ is the probability that (w, c) is from the true

[§]<https://code.google.com/archive/p/word2vec/>

corpus, $p(D = 0|w, c)$ is the probability that it did not and D' is the artificial corpus of negative pairs. Similarly to this negative sampling loss function the ranking objectives implemented in the approaches in Chapters 5 6 and ?? and described in detail in Section 2.5 force the model to match images i and corresponding sentences s and push contrastive examples (\hat{i}, s) and (i, \hat{s}) far from each other in the learned multi-modal space.

Finally the GloVe approach (Pennington et al., 2014) is another simple linear model with word $\mathbf{W}_w \in \mathbb{R}^{|V| \times d}$ and context $\mathbf{W}_c \in \mathbb{R}^{|V| \times d}$ embeddings, which represents a hybrid between count- and prediction-based techniques: it optimizes word-embeddings to predict the re-weighted log co-occurrence counts $\log(\#(w, c))$ collected from corpora D :

$$\mathbf{w}^T \mathbf{c} + b_w + b_c = \log(\#(w, c)) \quad \forall (w, c \in D) \quad (2.9)$$

where b_w and b_c are context specific bias terms. Now let us express the Glove model in the traditional re-weighted co-occurrence matrix factorization form. Let the matrix $M \in \mathbb{R}^{|V| \times |C|}$ store the log-weighted weighted counts and \mathbf{b}_w and \mathbf{b}_c be the vectors of all b_w and b_c scalars, then

$$M \approx \mathbf{W} \cdot \mathbf{C}^T + \mathbf{b}_w + \mathbf{b}_c \quad (2.10)$$

In fact there has been work on finding relationships between count- and prediction-based methods (Levy & Goldberg, 2014) and using insights from both to develop novel improved variants (Levy et al., 2015).

Visually grounded representations of words

Language and perception

The discussion of learning distributed representations so far has focused on implementations of the distributional hypothesis and extracting information exclusively from text corpora. To human language learners, however, a plethora of perceptual information is available to aid the learning process and to enrich their mental representations. The link between human word and concept representation and acquisition and the perceptual-motor systems has been well established through behavioral neuroscientific experiments (Pulvermüller, 2005). The earliest words children learn tend to be names of concrete perceptual phenomena such as objects, colors and simple actions (Bornstein et al., 2004). Furthermore, children generalize to the names of novel objects based on perceptual cues such as shape or color (Landau et al., 1998). In general, the *embodiment* based theories of concept representation and acquisition in the cognitive scientific literature put forward the view that a wide variety of cognitive processes are grounded in perception and action (Meteyard & Vigliocco, 2008). That said, the precise role of sensori-motor information in language acquisition and representation is a highly debated topic (Meteyard et al., 2012).

Motivated by such cognitive theories and experimental data various computational cognitive models of child language acquisition investigate the issue of learning word meanings from small scale or synthetic multi-modal data. The model presented by Yu (2005) uses visual information to learn the meanings of object names whereas the architecture of Roy (2002) learns to associate word sequences with

simple shapes in a synthetically generated data setting.

Interestingly even the articles introducing Latent Semantic Analysis (Landauer & Dumais, 1997) and Hyperspace Analogue to Language (Lund & Burgess, 1996) mention that a possible limitation of the presented distributional semantic models is the lack of grounding in extra-linguistic reality. Landauer & Dumais (1997) puts it as "But still, to be more than an abstract system like mathematics words must touch reality at least occasionally." The lack of relationship between symbols and the external reality is usually referred to as the *grounding problem* in the literature (Harnad, 1990; Perfetti, 1998). On the defense of purely textual models Louwerse (2011) argues that the corpora used to train distributional semantic models are generated by humans and as such reflect the perceptual world. For a counter argument consider how many pieces of text state obvious perceptual facts such as "bananas are yellow" or how often do objects holding the "yellow" property appear in similar textual contexts (Bruni et al., 2014).

In practice much work on multi-modal distributional semantics have found that text-only spaces tend to represent more encyclopedic knowledge, whereas multi-modal representations capture more concrete aspects (Andrews et al., 2009; Baroni & Lenci, 2008). In Chapter 3, where we develop a cross-situational cognitive model of word-learning, we also find that the word-representations learned by our model correlate better with human similarity judgements on more concrete words rather than. In contrast word-embeddings learned by the SGNS algorithm trained on the same sentences perform better on more abstract words.

One does not necessarily need to reach a conclusion on whether

grounded or distributional models are superior; combining their merits in a pragmatic way is an attractive alternative (Riordan & Jones, 2011).

Combined distributional and visual spaces

When learning multimodal word representations we wish to construct a matrix \mathbf{W} , where each row \mathbf{W}_i corresponds to a word and each feature column $\mathbf{W}_{:,j}$ represents a distributional feature, a perceptual feature or a mixture of the two.

The first approach to learn visual word representations from realistic data sets was introduced by Feng & Lapata (2010). They develop a multi-modal topic model trained on a BBC News based data set containing text articles with image illustrations. Each document considered by their model is a pair $\langle D, I \rangle$ with text document D and image I . The documents D are represented as bag-of-words vectors (BoW) – as common in the *count-based* distributional semantics framework – while images are represented as bag-of-visual-words (BoVW) (Csurka et al., 2004). The BoVW representations are obtained by first applying the difference-of-Gaussians point detector to segment images into local regions, which are then represented by SIFT features (Lowe, 1999). Finally, these extracted features are clustered with K-means resulting in the bag-of-visual-words representation i.e. a vector of counts, where each entry is the number of regions on the image that corresponds to a certain SIFT-cluster. Given both the BoW $\psi(D)$ and BoVW $\phi(I)$ feature functions each pair $\langle D, I \rangle$ can be represented as concatenation of the application of the two $[\psi(D), \phi(I)]$.

This if followed by training multi-modal topic model, specifically

Latent Dirichlet Allocation (Blei et al., 2003) on top of the joint representations of the documents and images. The hierarchical bayesian generative story of multi-modal LDA starts by sampling multi-modal topics, which then generate both the English words and visual words. After convergence each word is represented by a vector, where each component corresponds to the conditional probability of that word given a particular multi-modal topic. Feng & Lapata (2010) shows that the multi-modal LDA model outperforms the text-only LDA representations by a large-margin on word association and word-similarity experiments.

The perceptually grounded word representations of Bruni et al. (2012) also combines distributional semantic models and BoVW pipelines. Rather than having a collection of documents $\langle D, I \rangle$ they consider a set of words for, which both distributional and image features are available. For visual word representations they use images labeled with tags by annotators. Similarly to Feng & Lapata (2010) they apply the BoVW feature extraction pipeline with SIFT and color features to represent images. Contrary to Feng & Lapata (2010), however, a visual-only representation is created for each tag-word by summing over the features for all images corresponding to the tag. For text-only models they construct several types of distributional semantic spaces from text-only corpora unrelated to the images. Note that as in the previous example they wish to create a multimodal word representation and applied separate functions to extract textual ψ and visual ϕ features. Finally they create the multi-modal space through concatenation.

On word-similarity benchmarks they show that the text-only model performs better than visual-only and that the combination of the two

surpasses both. They also find that distributional semantics models perform poorly on finding the typical colors of concrete nouns, whereas the visual and multi-modal models perform perfectly. In these experiments distributional semantics models fail to capture the obvious fact that “the grass is green” providing evidence against the theoretical argument that perceptual information is available in large collections of texts and so grounded representations are superfluous (Louwerse, 2011).

Combining BoVW and count-based distributional word-representations remained the standard methodology in many other works on multi-modal word representations at the time (Bruni et al., 2011; Leong & Mihalcea, 2011a,b). Bruni et al. (2014) frames multi-modal distributional semantics under a general framework: create separate textual and visual features for words followed by re-weighting and matrix factorization. Researchers can apply vector-space models to create the distributional space \mathbf{W}^d and computer vision techniques to create visual feature representations for the same words \mathbf{W}^v . The separate feature spaces are mixed together first by concatenation $\mathbf{W} = [\mathbf{W}^d; \mathbf{W}^v]$, which is optionally followed by singular value decomposition to combine the two modalities.[¶]

This framing allows researchers to take advantage of evolving NLP and computer vision techniques and experiment by plugging in various distributional semantics methods as textual feature extractors ϕ and image processing techniques as ψ . For example Kiela & Bottou (2014) runs the SGNS algorithm on large text corpora and takes the word-embedding parameters $\mathbf{W}^d \in \mathbb{R}^{|V| \times d}$ as the distributional space

[¶]Note that discovering latent factors through the application of singular value decomposition on the concatenated textual and visual spaces is similar in spirit to applying topic models such as LDA.

and they apply pre-trained convolutional neural networks (CNN) as black-box image feature extractors. We apply CNNs as image feature extractors in all chapters.

These architectures learn a hierarchy of blocks of image filters followed by pre-defined pooling operations optimized for a particular task. It has been observed in the computer vision community that the lower layers of deep CNNs trained across various data sets and tasks tend to learn filter maps that resemble Gabor-filters and color-blobs. Intuitively these low-level features appear to be general and as such afford *transfer*. Around the time there was extensive work on exploring the transferability of CNN features to various computer vision tasks through fine-tuning (Donahue et al., 2014b; Oquab et al., 2014) or simply taking the last layer representation of CNNs as high-level features as inputs to linear classifiers (Girshick et al., 2014; Sharif Razavian et al., 2014). Given their success in transfer learning for vision it is natural to apply CNNs in the visually grounded language learning community as black-box image feature extractors. Similarly to Bruni et al. (2014) in Kiela & Bottou (2014) the visual features of words are computed as the summary the feature vectors extracted from all images they co-occur with $\mathbf{I} \in \mathbb{R}^{|V| \times i}$, where i is the size of the CNN image-embedding. Applying the simple concatenation operation to the two spaces $[\mathbf{W}; \mathbf{I}]$ they show that CNN features outperform BoVW features on word-similarity experiments with the multi-modal word-representations.

All approaches described so far require both visual and textual information for the same concepts. Furthermore, in (Bruni et al., 2014) and (Kiela & Bottou, 2014) textual and visual representations are learned separately and are fused later. The multi-modal skip-

gram Lazaridou et al. (2015) model was developed to alleviate such limitation: it is a multi-task extension of the skip-gram algorithm predicting both the context of words, but also the visual representations of concrete nouns. This optimizes word representations to be predictive of both their visual and textual contexts jointly. Ground truth visual representations are constructed by averaging the CNN representations Krizhevsky et al. (2012) of 100 pictures sampled from ImageNet Deng et al. (2009). This architecture was later proposed as a model of child language learning and was applied to the CHILDES corpus MacWhinney (2014) with modifications to model referential uncertainty and social cues Lazaridou et al. (2016) present in language learning. Later it was compared to human learning performance Lazaridou et al. (2017).

Chapter 3 presents a computational cognitive model of word learning using only visual information developed at the same time as the multi-modal skip-gram approach. Similarly to Feng & Lapata (2010) we assume pairs of text and images $\langle D, I \rangle$. However, in our data set images represent every day scenes and are paired with descriptive sentences to mimic the language environment of children on a high level. Our model implements the extreme literal of cross-situational language learning and assumes that the representations of words are learned exclusively through the co-occurrences between visual features and words. Rather than building a matrix of image-features per word and then summarizing as in Kiela & Bottou (2014), we apply an online expectation-maximization based (Dempster et al., 1977) algorithm to align words with image features mimicking child language learning. In essence, our approach combines the cross-situational incremental word-learning model of Fazly et al. (2010b) with the larger

realistic data sets, modern convolutional image representations and extends it to operate on real-valued scene representations. The result of the learning process is a word embedding matrix \mathbf{W}_i , where each row \mathbf{W}_i corresponds to a word, each column \mathbf{W}_j to a CNN feature and each entry $\mathbf{W}_{i,j}$ to the strength of the relationship between the word i and image-feature j . We show through word-similarity experiments that, while our approach performs on par with the SGNS trained on the same data set, there is a qualitative difference between the learned embeddings: our visual word-embeddings represent concrete nouns closer to human judgements than abstract nouns. As each word embedding \mathbf{W}_i is represented in the image-feature space we show that our model can label images with related nouns through simple nearest neighbor search.

From words to sentences

Applying the distributional intuition to model the meaning of sentences is not as straightforward as it is for words. Imagine building a sentence-embedding matrix \mathbf{W} where each row \mathbf{W}_i corresponds to a possible sentence i and each column \mathbf{W}_j to a feature j . How many rows should we include?

Intuitively, the number of words in a corpus is much lower than the number sentences: one can assume a large, but finite set of existing words and an infinite set of potential sentences to *compose* from them. Words can be thought of as *atomic units* and in downstream applications one can use a lookup operation on a word embedding matrix to represent units in the input. However, it is infeasible to lookup full sentences. In fact, from a method that represents sentences in a continuous space one would expect to also

represent and generalize to unseen sentences at test time. Furthermore, given two sentences *John loves Mary* and *Mary loves John* we wish our sentence encoding function ϕ to represent the meaningful difference stemming from the underlying syntactic structure $\phi(\textit{John loves Mary}) \neq \phi(\textit{Mary loves John})$. As such we seek to learn a sentence encoder ϕ that is sensitive to syntactic structure or in other words *compositionality* i.e.: the notion that the meaning of an expression is a function of its parts and the rules combining them (Montague, 1970).[¶]

The compositional distributional semantics framework produce continuous representations for phrases up to sentences using additive and multiplicative interactions of count-based distributed word-representations (Mitchell & Lapata, 2008) or combine symbolic and continuous representations with tensor-products (Clark & Pulman, 2007). The latter line of work culminated in a number of unified theories of distributional semantics and formal type logical and categorical grammars (Coecke et al., 2010; Clarke, 2012; Baroni et al., 2014a). These approaches assume that words are represented by distributional word embeddings and define compositional operators on top of them motivated by particular formal semantic considerations. From the point of view of theoretical linguistics arguably one of the most intriguing aspects of such theories of meaning is that they provide an elegant data driven solution to deal with the representation of the lexical entries of content words – nouns, verbs and adjectives. This is otherwise a major challenge in formal semantics requiring sophisticated formalisms such as typed λ -calculus with in-

[¶]Similarly one could argue that *morphemes* are atomic units from which words are composed from. In fact, sub-word representations form an important field of research (Bojanowski et al., 2017).

tricate and vast type-systems (Asher, 2011). Within applied NLP, however, this line of work have not resulted in practical machine learning approaches to solve natural language tasks on real world data sets. Likely this is due to the different scope and the computationally expensive high-order tensor operations involved (Bowman, 2016).

Lastly, before going forward with the more recent neural models in the next section, it is only fair to mention that bag-of-words based representations bypassing the issue of compositionality form a set of very strong baselines for a number of sentence level tasks (Hill et al., 2016). These simple baselines include using multinomial-naive bayes uni- and bi-gram log-count features within support vector machines (Wang & Manning, 2012) or feeding the average of the word-embeddings in a sentence into a softmax classifier (Joulin et al., 2016).

Neural sentence representations

In Section 2.1 we have discussed the feed-forward (Bengio et al., 2003) and recurrent network (Mikolov et al., 2010) language models from the perspective of learning word-representations. However, both architectures learn embeddings of not only single words, but also learn to represent of sequences of multiple words such as sentences. An intriguing property of such approaches is that they represent various linguistic objects in the same space as activations of the neural models.^{**} When learning transferable sentence representations there are

^{**}This property is not unique to neural models e.g. the pregroup algebra based compositional distributional semantics framework of Coecke et al. (2010) sentences of any grammatical structure live in the same inner-product space.

two main considerations we will discuss: 1.) which architecture to choose and 2.) what objective to optimize.

Various neural network architectures have been proposed that handle variable sized data structures useful for language processing: a.) recurrent networks take the input sequentially one word or character at a time b.) convolutional neural networks (Kalchbrenner et al., 2014; Zhang et al., 2015; Conneau et al., 2016; Chen et al., 2013) process sequences in fixed sized n-gram patterns up to a large window, c.) recursive neural networks (Goller & Kuchler, 1996; Socher et al., 2011; Tai et al., 2015b) take a tree data structure as input such as a sentence according to the traversal of a constituency d.) graph neural networks operate on graphs (Marcheggiani & Titov, 2017) such as syntactic/semantic-dependency or abstract meaning representations. All the aforementioned architectures take word-embeddings as input and compute fixed vectors for sentences. These representations are tuned to a specific task such as sequence tagging, sentence classification, machine translation or language modeling.

In Chapters 4, 5, 6 and ?? we decided to apply recurrent neural networks as sentence encoders. Recursive neural networks provide a principled approach to compute representations along the nodes of constituency or dependency parse trees (Socher et al., 2013, 2014; Le & Zuidema, 2015; Tai et al., 2015b). In practice, however, these architectures require parse trees as input, which makes them impractical for our mission of learning visually grounded representations for multiple languages. For each language considered, the training procedure requires finding a good pipeline from text pre-processing to parsing to generate the input representations for the networks. Furthermore, tree structures by nature do not afford straightforward batched com-

putation directly and tend to run dramatically slower than recurrent or convolutional models. In terms of performance the jury is still out, however, so far only modest improvements have been observed over recurrent models on specific tasks in specific settings (Li et al., 2015; Tai et al., 2015b). For graph structured neural networks the same argument holds. Two equally practical alternatives to RNNs that operate on raw sequences are convolutional neural networks (Bai et al., 2018) and transformers (Vaswani et al., 2017) and both could replace the RNNs in Chapters 5, 6 and ??.

As mentioned earlier contrary to word-embeddings the representations and the composition function these models learn are task specific and not *universal*. For learning transferable and general distributed sentence representations the first notable approach is the skip-thought vectors model (Kiros et al., 2015). It extends distributional semantics intuition to the sentence level: they train a sentence encoder on contiguous sentence sequences – such as books – and learns sentence representations predictive of the sentences around it. More specifically they train a recurrent encoder to encode sentence s_i and use two separate recurrent decoders to generate the pre-context s_{i-1} and post-context s_{i+1} . This method was confirmed to be a successful self-supervised method for transfer learning in a number of sentence classifications tasks beating simpler approaches such as bag-of-words approaches based on skip-gram or CBOW embeddings, tf-idf vectors and auto-encoders (Hill et al., 2016). A convolutional variant of the encoder was introduced in Gan et al. (2016) and several other works train simple sum/average pre-trained word-embedding encoders using the same sentential context prediction objective (Kenter et al., 2016; Hill et al., 2016). The larger context of paragraphs is

explored in Jernite et al. (2017) where the task is to predict discourse coherence labels in a self-supervised fashion.

Some later approaches have moved away from distributional cues and identified supervised tasks that lead to representations that transfer well to a wide variety of other tasks. The task of Natural Language Inference (Bowman et al., 2015; Williams et al., 2017b) as an objective was identified to learn good sentence embeddings (Conneau et al., 2017; Kiros & Chan, 2018) and Subramanian et al. (2018) combines a number of other supervised tasks with self-supervised training through multi-task learning.

The state-of-the-art in learning universal sentence representations at the time of writing is represented by neural language models with a large number of parameters trained over huge corpora (Peters et al., 2018; Devlin et al., 2018). These approaches go back to exploiting only distributional cues and train a stack of convolutional and/or recurrent and/or transformer layers on large-scale language modeling. When transferring the networks to novel tasks these networks are either fine-tuned, a separate smaller network is trained on top of their representations or they are used as fixed feature extractors (Howard & Ruder, 2018; Peters et al., 2019).

Visually grounded sentence representations

Universal sentence representations are in general learned from text-only corpora. The most successful current trend being large-scale language modeling based on the distributional semantics intuition of the general usefulness of linguistic context prediction. However, this leaves the resulting sentence representations blind to the language-external reality leading to the grounding problem as discussed in

Section 2.2. Given that visual information has been shown to contain useful information for word-representations it is a natural question to ask whether this observation generalizes to sentence embeddings. The idea of context prediction coming from the distributional hypothesis can be adopted to visual grounding in a conceptually straightforward manner: train sentence embeddings to be predictive of their visual context.

The larger family of techniques that our visually grounded sentence learning approach technically belongs to is *learning to rank* (Li, 2011). Some of the earlier attempts at multi-modal ranking did not consider full sentences rather images paired with (mostly) noun tags such as Weston et al. (2010).

Framing the learning of multi-modal vision and language spaces as a ranking problem from images to descriptions and conversely from descriptions to images was put forward by Hodosh et al. (2013a). They argue that evaluating grounded learning through image–description generation is plagued by the lack of straightforward performance measures. This issue was later discussed in Elliott & Keller (2014) who demonstrate low to moderate correlation between automatic measures such as BLUE, METEOR and ROUGE with human judgements.

From the image–sentence ranking perspective a joint space between language and vision reflects accurately the underlying semantics if given one modality as *query* the other modality can be accurately *retrieved*. This leads to a straightforward evaluation protocol adopting metrics from information retrieval literature such as Recall@N, Precision@N, Mean Reciprocal Rank, Median Rank or Mean Rank. From the practical point of view it also unifies image–

annotation and image–search based on language queries.

The standard benchmark data sets we used for this purpose annotate images found in online resources with descriptions through crowd-sourcing. These descriptions are largely *conceptual*, *concrete* and *generic*. This means that descriptions do not focus too much on *perceptual* information such as colors, contrast or picture quality; they do not mention many *abstract* notions about images such as mood and finally the descriptions are not *specific* meaning that they do not mention the names of cities, people or brands of objects. What they do end up mentioning are entities depicted in the images (frisbee, dog, boy) their attributes (yellow, fluffy, young) and the relations between them. The images depict common real-life scenes such as a *bus turning left* or *people playing soccer in the park*. As such, annotation collected independently from different crowd-source workers end up focusing on different aspects of these scenes^{††}.

Following the ranking formulation of grounded learning by (Hodosh et al., 2013a) the earliest works applying a combination of sentence and image encoder neural networks to image–sentence ranking were put forward by Kiros et al. (2014) and Socher et al. (2014): they both apply pre-trained convolutional neural networks as image encoders and while Socher et al. (2014) use recursive neural network variants to encode sentences Kiros et al. (2014) apply recurrent networks. Rather than matching whole images with full sentences the alternative approach of learning latent alignments between image–regions and sentence fragments have also been explored concurrently (Karpathy et al., 2014; Karpathy & Fei-Fei, 2015).

Following (Kiros et al., 2014) to predict images from the sentences

^{††}For a comprehensive overview on image-description data sets please consult Bernardi et al. (2016)

– and conversely sentences from the images – the architecture we chose in Chapters 4, 5, 6 and ?? combines a recurrent neural network $\phi(s, \theta)$ to represent sentences s and a pre-trained convolutional neural networks followed by an affine transformation we train for the task $\psi(i, \theta)$ to extract features from images i . The image-context prediction from sentences in Chapter 4 is formulated as minimizing the cosine distance between the learned sentence $\mathbf{s} = \phi(s, \theta)$ and image representations $\mathbf{i} = \psi(i, \theta)$ in a training set of image–caption pairs $\in D$:

$$J_{cos}(\theta) = \sum_{\in D} 1 - \frac{\mathbf{i} \cdot \mathbf{s}}{\|\mathbf{i}\| \|\mathbf{s}\|} \quad (2.11)$$

Later we follow the formulations of Vendrov et al. (2015) and Faghri et al. (2017) and apply the sum-of-hinges loss in Chapter 5 and max-of-hinges ranking objective in Chapters 6 and ?? . These loss functions push relevant pairs $$ close, while contrastive pairs $$ and $<\hat{i}, s>$ far from each other in a joint embedding space. Given a mini-batch of e.g. 100 samples, for each sample the contrastive pairs are generated by taking the wrong pairings from that batch leading to 99 contrastive pair per sample. The ranking losses are minimized in both directions:

$$J_{rank}(\theta) = \sum_{\in D} f_{rank}(\mathbf{i}, \mathbf{s}) + f_{rank}(\mathbf{s}, \mathbf{i}) \quad (2.12)$$

where the f_{rank} is either the sum-of-hinges loss J_{sum}

$$J_{sum}(\theta) = \sum_{<\hat{a}, b>} [\max(0, \alpha - s(\mathbf{a}, \mathbf{b}) + s(\hat{\mathbf{a}}, \mathbf{b}))] \quad (2.13)$$

or the max-of-hinges objective:

$$J_{max}(\theta) = \max_{\langle \hat{\mathbf{a}}, \mathbf{b} \rangle} [\max(0, \alpha - s(\mathbf{a}, \mathbf{b}) + s(\hat{\mathbf{a}}, \mathbf{b}))] \quad (2.14)$$

where α is the margin parameter for both loss functions and $s(a, b)$ is the cosine similarity function. We empirically found both ranking losses to perform better than J_{cos} and J_{max} to perform consistently better in our experiments than J_{sum} . The use of these various objectives across chapters reflects the evolving common practices in the field at the time.

The representations learned by such image–sentence ranking models have been shown to improve performance when combined with skip-thought embeddings on a large number of semantic sentence classifications tasks compared to skip-thought only (Kiela et al., 2017). These findings were confirmed and improved upon using a self-attention mechanism on top of the RNN encoder (Yoo et al., 2017).

In Chapter 4 we develop methods to investigate the difference between the representations learned by (text-only) language models and image–sentence ranking models. Next in Chapter 5 we show that incorporating the visually grounded learning through an image–sentence ranking objective leads to better translations in the visually descriptive domain. Furthermore, we show that learning multi-modal representations provides gains on top of learning from larger bilingual corpora. Finally in Chapters 6 and ?? we apply this framework in the multi-lingual setting and demonstrate that better visually grounded representations can be learned when training on multiple languages jointly.

Visually grounded multilingual representations

On top of the visual modality anchoring linguistic representations to perceptual reality it also provides a universal meaning representation bridging between languages. The intuition being that words or sentences with similar meanings appear within similar perceptual contexts independently of the language. First in Section 2.6.1 we discuss the multi-view representation learning perspective of considering images annotated with multiple descriptions in different languages as multiple views of the same underlying semantic concepts. Our aim in Chapters 6 and ?? is to learn better visually grounded sentence representations by learning from these multiple-views simultaneously. Furthermore, in Chapter 5 we show that we can improve translation performance by learning better sentence representations through adding the visual modality as an additional view. Next we discuss how images can be used as pivots in practice for translation on word-level in Section 2.6.2 and on sentence-level in Section 2.6.3.

Multi-view representation learning perspective

Images and their descriptions in multiple languages can be taken as different views of the same underlying semantic concepts. From this multi-view perspective learning common representations of multiple languages and perceptual stimuli can potentially exploit the complementary information between views to learn better representations. Being able to extract a shared representation from only a single view also leads to practical applications such as cross-modal and cross-lingual retrieval or similarity calculation.

Multi-view learning traditionally considers paired samples \mathbf{X} and

\mathbf{Y} , where each pair of rows $\langle \mathbf{x}_i \in \mathbf{X}, \mathbf{y}_i \in \mathbf{Y} \rangle$ are two measurements of the same underlying phenomena. In other words we assume two sets of variables representing the same data point. The two main multi-view learning paradigms put forward in recent literature are based on autoencoders and canonical correlation analysis (CCA) (Wang et al., 2015).

To illustrate the autoencoder approach let us consider Ngiam et al. (2011) who introduced the idea of multi-modal autoencoders to learn multi-modal joint representations of audio and video. Let ϕ be an encoder neural network extracting features from both modalities and ψ and χ be modality specific decoders. Their model performs the following optimization:

$$\min_{\theta_\phi, \theta_\psi, \theta_\chi} \frac{1}{N} \sum_i^N (||X_i - \psi(\phi(X_i))||^2 + ||Y_i - \chi(\phi(Y_i))||^2) \quad (2.15)$$

where $\theta_\phi, \theta_\psi, \theta_\chi$ are the encoder and decoder parameters and N is the size of the training set. This approach learns shared representations such that one view can be reconstructed from another. Autoencoder approaches remain one of the standard family of models to study the learning of visual-linguistic multi-modal spaces (Silberer & Lapata, 2014; Silberer et al., 2017; Wang et al., 2018).

For the discussion of CCA based approaches let us consider the deep canonical correlation analysis (DCCA) put forward by Andrew et al. (2013). In this approach view specific networks ψ and ϕ are applied to extract non-linear features and the canonical correlation between these representations is maximized:

$$\max_{\theta_\phi, \theta_\psi, \mathbf{U}, \mathbf{V}} \frac{1}{N} \text{tr}(\mathbf{U}^T \phi(\mathbf{X}) \psi(\mathbf{Y}) \mathbf{V}^T) \quad (2.16)$$

$$\text{subject to } \mathbf{U}^T \left(\frac{1}{N} \phi(\mathbf{X}) \phi(\mathbf{X})^T + r_x \mathbf{I} \right) = \mathbf{I} \quad (2.17)$$

$$\mathbf{V}^T \left(\frac{1}{N} \psi(\mathbf{Y}) \psi(\mathbf{Y})^T + r_y \mathbf{I} \right) = \mathbf{I} \quad (2.18)$$

$$\mathbf{u}_i^T \phi(\mathbf{X}) \psi(\mathbf{Y}) \mathbf{v}_j = 0, \quad \forall_{i,j} \quad i \neq j \quad (2.19)$$

Here θ_ϕ, θ_ψ are neural network parameters, r_x, r_y are regularization parameteres (De Bie & De Moor, 2003) and \mathbf{U}, \mathbf{V} are projection matrices or *directions* of the CCA. This optimization process amounts to maximizing the correlation between the projections of the two data views subject to the constraint that the projected dimensions are uncorrelated.

The *workhorse* of the image–sentence ranking experiments of (Hodosh et al., 2013a) was in fact the Kernel CCA method (Akaho, 2006). Other CCA based approaches were also applied to the image–sentence data sets we consider in our work (Gong et al., 2014; Klein et al., 2015; Eisenschat & Wolf, 2017).

A third direction that is also explored is combining the reconstruction objective of autoencoders with an additional correlation loss, but without the whitening constraints of CCA (AP et al., 2014; Chandar et al., 2016).

In the multi-lingual multi-modal setting Funaki & Nakayama (2015) applies Generalized CCA (Horst, 1961) – a variant of CCA generalized to multiple views as opposed to only two – to learn correlated representations of images and multiple languages. The deep partial

canonical correlation analysis approach – a deep learning extension of the partial canonical correlation (Rao, 1969) – learns multilingual English-German sentence embeddings conditioned on the representation of the images they are aligned to (Rotman et al., 2018). They show that their model using the visual modality as an extra view finds better multilingual sentence and word representations as demonstrated by cross-lingual paraphrasing and word-similarity results.

The bridge correlational neural network approach (Rajendran et al., 2015) combines autoencoders and correlation objectives to learn common representations in a setting when the different views only need to be aligned with one pivot view. They preform image-sentence retrieval experiments in French or German where the image-caption data set is only available for English, however, there is parallel corpora between German or French and English. In other words English acts as a pivot. A similar combination of autencoder and correlational training was applied to *bridge* image–captioning (Saha et al., 2016a).

Our formulation of the problem does not fall in the set of approaches generally considered as multi-view learning. However, it is similar to the CCA based techniques in that we train two sub-networks – one for the linguistic ψ and another for the image modality ϕ – and do not rely on decoder networks to compute a reconstruction loss as in the autoencoder approaches. Furthermore in Chapter 4 we minimize the cosine distance between the learned representations which is related to the CCA objective: when the matrices \mathbf{X} and \mathbf{Y} are not centered the CCA objective corresponds to maximizing the cosine similarity instead of the correlation.

One of the main benefits of the learning to rank approach we opted for is its flexibility: 1.) in Chapter 4 we train an image–sentence

ranking model in a single language, 2.) we apply the same building blocks to train on multiple languages where the same images are shared between languages in Chapter 6, 3.) in Chapter ?? we explore the setup without such an alignment and finally 4.) in Chapter 5 we improve the automatic translation performance by adding the image–sentence ranking objective, incorporating an additional view to help us learn better sentence representations.

In our setup additional views are incorporated in the sentence representations by full parameter sharing with multi-task learning: given multiple image–caption data sets at each iteration we sample a batch from one of them and perform an update to θ_ϕ and θ_ψ using the ranking loss function. Gella et al. (2017) applies the image–sentence ranking framework in the multilingual setup considering images as a pivots bridging English and German and train a multilingual image–sentence ranking model. Their results suggest that the multilingual models outperform the monolingual ones on image-sentence ranking, however, they do not show consistent gains across languages and model settings. In Chapter 6 we implement a similar setup to Gella et al. (2017) and show that both English and German image-sentence ranking performance is reliably improved by bilingual joint training using our setup. We expand on the results further and provide evidence that more gains can be achieved by adding more views: on top of English and German, we add French and Czech captions and show the monolingual model is consistently outperformed by the bilingual and the latter by the multilingual. We apply the same approach to improve the performance on the lower resource French and Czech languages by adding the larger English and German image-caption sets; showing successful multilingual transfer in the vision-language

domain.

Bilingual lexicon induction

On word level images have been used to link languages and induce bilingual lexicons without parallel corpora. The lack of bi-text in this setting have been traditionally solved by methods relying on textual features such as orographic similarity (Haghghi et al., 2008) or similar diachronic distributional statistical trends between words (Schafer & Yarowsky, 2002). However, images tagged with various labels in a multitude of languages are available on the internet and a model of image-similarity can be used to exploit images as pivots to find translations between such tags. Alternatively representing words in multiple languages in a joint space with images – as discussed in Section 2.2 for the monolingual case – allows word translation to be simply performed through nearest neighbour search.

The first approach to construct a dictionary based on image similarity was developed by Bergsma & Van Durme (2011). They use Google image search to find relevant images for the names of physical objects in multiple languages. These images are represented by BoVW vectors based on SIFT and color features. To find word-translations given a word in the source language and a list of possible translations in the target language for each word Google is queried to find n images per word. For each image the feature vectors are extracted. This is followed by computing the similarity between the feature vectors of the images corresponding to the source word and all target words. Finally the word in the target vocabulary with the highest similarity is chosen.

This method is vastly improved upon by a later approach applying

pre-trained convolutional neural networks to represent words in the visual space (Kiela et al., 2015). Their approach closely follows the monolingual visual-word representations of Kiela et al. (2014): each word is represented as the summary of CNN representations of images they co-occur with. Given a word in the source word the candidate translation is found simply by performing nearest neighbor search on the target vocabulary.

Exploring the limitations of image-pivoting for bilingual lexicon induction Hartmann & Søgaard (2017) present a negative result showing that such techniques scale poorly to non-noun words such as adjectives or verbs. However, combining image-pivot based bilingual word-representations with more traditional multi-lingual word-embedding techniques lead to superior performance compared to their uni-modal counterparts Vulić et al. (2016).

At the time of writing this thesis the first large-scale vision based bilingual dictionary induction data set was put forward by (Hewitt et al., 2018). They create a data set of 200K words and 100 images per each using Google Image Search and perform experiments with 32 languages. They confirm the finding of Hartmann & Søgaard (2017) that image-pivoting is most effective for nouns, however, find that using their larger data set adjectives can also be translated reliably. Similarly to Vulić et al. (2016) they also show that combining visual and textual word-representations through a re-ranking experiment that visual representations improve the state-of-the-art text-only methods in the case of *concrete* concepts.

Image pivots for translation

In automatic machine translation a pivot based approach is applied when there are parallel corpora available between language pairs $A \rightarrow C$. and $C \rightarrow B$, but there is no data for $A \rightarrow B$. The problem is solved by first translating A to C and then C to B . Image-pivoting refers to a setup where we assume the existence of a data set of images paired with words or sentences in different languages $A \leftrightarrow I_A$ and $B \leftrightarrow I_B$ and translation is done through the image space going through $A \rightarrow I$ to $I \rightarrow C$. Nakayama & Nishida (2017a) apply image-pivoting in such a zero-resource machine translation setting. The task is to translate from English to German without aligned parallel corpora, however, separate image-description data sets are available in both languages. They solve the problem by training two components: 1.) visual-sentence encoder that matches images and their descriptions, 2.) image-description generator maximizing the likelihood of gold standard captions given the images. At test time the visual-sentence encoder representation of the source sentence is fed to the image-description generator to produce the translation. Their results were improved later by modeling the image-pivot based zero-resource translation setup as a multi-agent communication game between encoder and decoder (Chen et al., 2018; Lee et al., 2017b).

Interpreting continuous representations

The linguistic representations learned through neural architectures are notoriously opaque. Contrary to count-based methods the features extracted by deep networks from text input appear as arbitrary dense vectors to the human eye. In experiments with grounded learn-

ing throughout this thesis we find that visual grounding improves translation performance and that multilingual representations outperform monolingual ones in image–sentence ranking. But where do these improvement come from? What are the linguistic regularities represented in the recurrent states that lead to the final performance metrics? Did the model learn to exploit trivial artifacts in the training data or did it learn to meaningfully generalize? What characterizes the individual features recurrent networks extract from the input sentences?

The main topic of this thesis is learning visually grounded representations for linguistic units. For a complete picture, however, it is crucial to assess the difference in the representations between textual only and multimodal representations not only from a quantitative point of view, but also from a qualitative linguistics angle. This is what Chapter 4 is dedicated to.

Developing techniques for interpreting machine learning models have multiple goals. From the practical point of view as learning algorithms make their way into critical applications such as medicine humans and machines need to be able to co-operate to avoid catastrophic outcomes (Caruana et al., 2015). As such there is a growing interest in deriving methods to *explain* the decision of such architectures.

One of the approaches is to assign a real-valued "relevance" score to each unit in the input signal, signifying how much impact it had on the final prediction of the model. One of the first paradigms in generating such relevance scores is gradient based methods: they take the gradient of the output of the network with respect to the input Simonyan et al. (2013). Deep neural models of language tasks

learn distributed representations of input symbols and as such further operations have to be applied to reduce the resulting gradient vectors to single scalars e.g.: using ℓ_2 norm (Bansal et al., 2016).

Another prominent and well studied approach still based on gradient information is layerwise relevance propagation (LRP) (Bach et al., 2015). The output of the final layer is written as the sum of the relevance-scores from the input and similarly to the back-propagation algorithm the relevance of each neuron recursively depends on the lower-layer all the way down to the input signal. Different versions of LRP run the backward pass with different rules taking as input gradient information and activation values. It was later theoretically analyzed and generalized into the deep Taylor decomposition method (Binder et al., 2016).

Perturbation based methods are gradient free and are algorithmically very simple: they involve generating pseudo-samples according to some procedure and measuring how the models' response changes between each pseudo-sample and the original. LIME (Ribeiro et al., 2016) and its NLP specific LIMSE extension (Poerner et al., 2018b) perturbs the input creating a local neighborhood around it and fits interpretable linear models to explain the predictions of any complex black box classifier. Even simpler perturbation based techniques measure the difference between the original input and the various perturbed candidates such as the erasure (Li et al., 2016b) and our omission (Kdr et al., 2016) method in Chapter 4.

Apart from practical considerations of model interpretation training complex and opaque models from close to raw input can help us discover interesting patterns in the input data that are crucial in solving the task. Deep neural networks learn to solve tasks from close

to raw input, similar to what humans receive. As such the regularities they learn can also shed light into the patterns humans might extract from data to cope with certain tasks. Recent methodology in probing the learned representations of LSTM language models, in fact, resemble psycholinguistic studies. A number of experiments using the agreement prediction paradigm (Bock & Miller, 1991) suggest that LSTM language models successfully learn syntactic regularities as opposed to memorizing surface patterns (Linzen et al., 2016; Enguehard et al., 2017; Bernardy & Lappin, 2017; Gulordava et al., 2018).

For our purposes in Chapter 4 we develop our explanation method to shed light on the linguistic characteristics of the input grounded learning models learn in contrast to text-only language models.

Chapter

Other publications completed during my PhD

Worked on some of the experiments for the visually grounded sentence representation learning model IMAGINET, which formed the basis in the investigations of Chapter 4:

- Chrupaa, G., Kdr, A., & Alishahi, A. (2015a). Learning language through pictures. *arXiv preprint arXiv:1506.03694*

Other than methods I also contributed to two corpora within the vision and language domain. During my internship at Microsoft Research Montreal my side-project was a synthetically generated visual-reasoning dataset named FigureQA:

- Kahou, S. E., Michalski, V., Atkinson, A., Kadar, A., Trischler, A., & Bengio, Y. (2017). Figureqa: An annotated figure dataset for visual reasoning. *arXiv preprint arXiv:1710.07300*

The second corpus I worked on was with our sister group in the communications department and a collaboration with Vrije Universiteit Amsterdam: a data set of native Dutch spoken image-description

with eye-tracking recordings. The goal of this project was to provide a large data set for the community interested in referring-expression research with rich annotations already existing in the Visual Genome data set:

- van Miltenburg, E., Kádar, A., Koolen, R., & Krahmer, E. (2018). Didec: The dutch image description and eye-tracking corpus. In *Proceedings of the 27th International Conference on Computational Linguistics* (pp. 3658–3669)

Outside of the vision and language domain I had the chance to explore other related topics. Within our research group, we published on learning unsupervised sentence representations from speech:

Chrupalá, G., Gelderloos, L., Kádár, Á., & Alishahi, A. (2018). On the difficulty of a distributional semantics of spoken language. *arXiv preprint arXiv:1803.08869*

Furthermore, we published a paper about attempting reproduce a recurrent architecture for language modeling:

- Kádár, Á., Côté, M.-A., Chrupalá, G., & Alishahi, A. (2018a). Revisiting the hierarchical multiscale lstm. In *Proceedings of the 27th International Conference on Computational Linguistics* (pp. 3215–3227)

I had the opportunity to work on implementing recurrent networks for generation in the context of referring-expression generation:

- Ferreira, T. C., Moussallem, D., Kádár, Á., Wubben, S., & Krahmer, E. (2018). Neuralreg: An end-to-end approach to referring expression generation. *arXiv preprint arXiv:1805.08093*

Finally, the largest project other than my main PhD project I worked on was during my main project during my Microsoft Research Montreal internship. It is linear-logic programming based system for generating text-based adventure games to test generalization in (deep) reinforcement learning:

- Côté, M.-A., Kádár, Á., Yuan, X., Kybartas, B., Barnes, T., Fine, E., Moore, J., Hausknecht, M., El Asri, L., Adada, M., et al. (2018). Textworld: A learning environment for text-based games. *arXiv preprint arXiv:1806.11532*

Learning word meanings from images of natural scenes

Abstract Children early on face the challenge of learning the meaning of words from noisy and ambiguous contexts. Utterances that guide their learning are emitted in complex scenes rendering the mapping between visual and linguistic cues difficult. A key challenge in computational modeling of the acquisition of word meanings is to provide representations of scenes that contain sources of information and statistical properties similar in complexity to natural data. We propose a novel computational model of cross-situational word learning that takes images of natural scenes paired with their descriptions as input and incrementally learns probabilistic associations between words and image features. Through a set of experiments we show that the model learns meaning representations that correlate with

human similarity judgments, and that given an image of a scene it produces words conceptually related to the image.

This chapter is based on Castro Ferreira, T., Krahmer, E., & Wubben, S. (2016). Individual variation in the choice of referential form. In *Proceedings of the 2016 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies*, NAACL-HLT'2016 (pp. 423-427). San Diego, California: Association for Computational Linguistics.

Introduction

Children learn most of their vocabulary from hearing words in noisy and ambiguous contexts, where there are often many possible mappings between words and concepts. They attend to the visual environment to establish such mappings, but given that the visual context is often very rich and dynamic, elaborate cognitive processes are required for successful word learning from observation. Consider a language learner hearing the utterance “*the gull took my sandwich*” while watching a bird stealing someone’s food. For the word *gull*, such information suggests potential mappings to the bird, the person, the action, or any other part of the observed scene. Further exposure to usages of this word and relying on structural cues from the sentence structure is necessary to narrow down the range of its possible meanings.

Cross-situational learning

A well-established account of word learning from perceptual context is called cross-situational learning, a bottom-up strategy in which the learner draws on the patterns of co-occurrence between a word and its referent across situations in order to reduce the number of possible mappings Quine (1960); Carey (1978); Pinker (1989). Various experimental studies have shown that both children and adults use cross-situational evidence for learning new words Yu & Smith (2007); Smith & Yu (2008); Vouloumanos (2008); Vouloumanos & Werker (2009).

Cognitive word learning models have been extensively used to study how children learn robust word-meaning associations despite

the high rate of noise and ambiguity in the input they receive. Most of the existing models are either simple associative networks that gradually learn to predict a word form based on a set of semantic features Li et al. (2004); Regier (2005), or are rule-based or probabilistic implementations which use statistical regularities observed in the input to detect associations between linguistic labels and visual features or concepts Siskind (1996); Frank et al. (2007); Yu (2008); Fazly et al. (2010b). These models all implement different (implicit or explicit) variations of the cross-situational learning mechanism, and demonstrate its efficiency in learning robust mappings between words and meaning representations in presence of noise and perceptual ambiguity.

However, a main obstacle to developing realistic models of child word learning is lack of resources for reconstructing perceptual context. The input to a usage-based cognitive model must contain the same information components and statistical properties as naturally-occurring data children are exposed to. A large collection of transcriptions and video recordings of child-adult interactions has been accumulated over the years MacWhinney (2014), but few of these resources provide adequate semantic annotations that can be automatically used by a computational model. As a result, the existing models of word learning have relied on artificially generated input Siskind (1996). The meaning of each word is represented as a symbol or a set of semantic features that are selected arbitrarily or from lexical resources such as WordNet Fellbaum (1998), and the visual context is built by sampling these symbols. Some models add additional noise to data by randomly adding or removing meaning symbols to/from the perceptual input Fazly et al. (2010b).

Carefully constructed artificial input is useful in testing the plausibility of a learning mechanism, but comparisons with manually annotated visual scenes show that these artificially generated data sets often do not show the same level of complexity and ambiguity as naturally occurring perceptual context Matusevych et al. (2013); Beekhuizen et al. (2013).

Learning meanings from images

To investigate the plausibility of cross-situational learning in a more naturalistic setting, we propose to use visual features from collections of images and their captions as input to a word learning model. In the domain of human-computer interaction (HCI) and robotics, a number of models have investigated the acquisition of terminology for visual concepts such as color and shape from visual data. Such concepts are learned based on communication with human users Fleischman & Roy (2005); Skocaj et al. (2011). Because of the HCI setting, they need to make simplifying assumptions about the level of ambiguity and uncertainty about the visual context.

The input data we exploit in this research has been used for much recent work in NLP and machine learning whose goal is to develop multimodal systems for practical tasks such as automatic image captioning. This is a fast-growing field and a detailed discussion of it is beyond the scope of this paper. Recent systems include (Karpathy et al., 2014), (Mao et al., 2014b), (Kiros et al., 2014), (Donahue et al., 2014a), (Vinyals et al., 2014), (Venugopalan et al., 2014), (Chen & Zitnick, 2014), (Fang et al., 2014). The majority of these approaches rely on convolutional neural networks for deriving representations of visual input, and then generate the captions using various ver-

sions of recurrent neural network language models conditioned on image representations. For example (Vinyals et al., 2014) use the deep convolutional neural network of (Szegedy et al., 2014) trained on ImageNet to encode the image into a vector. This representation is then decoded into a sentence using a Long Short-Term Memory recurrent neural network Hochreiter & Schmidhuber (1997). Words are represented by embedding them into a multidimensional space where similar words are close to each other. The parameters of this embedding are trainable together with the rest of the model, and are analogous to the vector representations learned by the model proposed in this paper. The authors show some example embeddings but do not analyze or evaluate them quantitatively, as their main focus is on the captioning performance.

Perhaps the approach most similar to ours is the model of (Bruni et al., 2014). In their work, they train multimodal distributional semantics models on both textual information and bag-of-visual-words features extracted from captioned images. They use the induced semantic vectors for simulating word similarity judgments by humans, and show that a combination of text and image-based vectors can replicate human judgments better than using uni-modal vectors. This is a batch model and is not meant to simulate human word learning from noisy context, but their evaluation scheme is suitable for our purposes.

(Lazaridou et al., 2015) propose a multimodal model which learns word representations from both word co-occurrences and from visual features of images associated with words. Their input data consists of a large corpus of text (without visual information) and additionally of the ImageNet dataset Deng et al. (2009) where images are labeled

with WordNet synsets.* Thus, strictly speaking their model does not implement cross-situational learning because a subset of words is unambiguously associated with certain images.

Our study

In this paper we investigate the plausibility of cross-situational learning of word meanings in a more naturalistic setting. Our goal is to simulate this mechanism under the same constraints that humans face when learning a language, most importantly by learning in a piecemeal and incremental fashion, and facing noise and ambiguity in their perceptual environment. (We do not investigate the role of sentence structure on word learning in this study, but we discuss this issue in Section 3.5).

For simulation of the visual context we use two collections of images of natural scenes, Flickr8K (F8k) Rashtchian et al. (2010) and Flickr30K (F30k) Young et al. (2014), where each image is associated with several captions describing the scene. We extract visual features from the images and learn to associate words with probability distributions over these features. This has the advantage that we do not need to simulate ambiguity or referential uncertainty – the data has these characteristics naturally.

The challenge is that, unlike in much previous work on cross-situational learning of word meanings, we do not know the ground-truth word meanings, and thus cannot directly measure the progress and effectiveness of learning. Instead, we use indirect measures such as (i) the correlation of the similarity of learned word meanings to

*The synsets of WordNet are groups of synonyms that represent an abstract concept.

word similarities as judged by humans, and (ii) the accuracy of producing words in response to an image. Our results show that from pairings of scenes and descriptions it is feasible to learn meaning representations that approximate human similarity judgments. Furthermore, we show that our model is able to name image descriptors considerably better than the frequency baseline and names a large variety of these target concepts. In addition we present a pilot experiment for word production using the ImageNet data set and qualitatively show that our model names words that are conceptually related to the images.

Word learning model

Latest existing cross-situational models formulate word learning as a translation problem, where the learner must decide which words in an utterance correspond to which symbols (or potential referents) in the perceptual context Yu & Ballard (2007); Fazly et al. (2010b). For each new utterance paired with a symbolic representation of the visual scene, first the model decides which word is *aligned* with which symbol based on previous associations between the two. Next, it uses the estimated alignments to update the meaning representation associated with each word.

We introduce a novel computational model for cross-situational word learning from captioned images. We reformulate the problem of learning the meaning of words as a translation problem between words and a *continuous* representation of the scene; that is, the visual features extracted from the image. In this setting, the model learns word representations by taking images and their descriptions one pair at a time. To learn correspondences between English words and im-

age features, we borrow and adapt the translation-table estimation component of the IBM Model 1 Brown et al. (1993). The learning results in a translation table between words and image-features, i.e. a list of probabilities of image-features given a word.

Visual input

The features of the images are extracted by training a 16-layer convolutional neural network (CNN) Simonyan & Zisserman (2014) on an object recognition task.[†] The network is trained to discriminate among 1,000 different object labels on the ImageNet dataset Deng et al. (2009). The last layer of the CNN before the classification layer contains high level visual features of the images, invariant to particulars such as position, orientation or size. We use the activation vector from this layer as a representation of the visual scene described in the corresponding caption. Each caption is paired with such a 4,096-dimensional vector and used as input to a cross-situational word learner. Figure 3.1 shows three sample images from the F8k dataset most closely aligned with a particular dimension, as measured by the cosine similarity between the image and a unit vector parallel to the dimension axis. For example, dimension 1,000 seems to be related to water, 2,000 to dogs or perhaps grass, and 3,000 to children.

[†]We used the F8k and F30k features available at <http://cs.stanford.edu/people/karpathy/deepimagesent/> and the data handling utilities from <https://github.com/karpathy/neuraltalk> for our experiments. The pre-trained CNN can be used through the Caffe framework Jia et al. (2014) and is available at the ModelZoo <https://github.com/BVLC/caffe/wiki/Model-Zoo>.

Figure 3.1: Dimensions with three most closely aligned images from F8k.

Learning algorithm

We adapt the IBM model 1 estimation algorithm in the following ways[‡]: (i) like (Fazly et al., 2010b) we run it in an online fashion, and (ii) instead of two sequences of words, our input consists of one sequence of words on one side, and a vector of real values representing the image on the other side. The dimensions are indexes into the visual feature “vocabulary”, while the values are interpreted as weights of these “vocabulary items”. In order to get an intuitive understanding of how the model treats the values in the feature vector, we could informally liken these weights to word counts. As an example consider the following input with a sentence and a vector of 5 dimensions (i.e. 5 features):

- The blue sky
- $(2, 0, 2, 1, 0)$

Our model treats this equivalently to the following input, with the values of the dimensions converted to “feature occurrences” of each feature f_n .

- The blue sky
- $f_1 f_1 f_3 f_3 f_4$

The actual values in the image vectors are always non-negative, since they come from a rectified linear (ReLU) activation. However, they can be fractional, and thus strictly speaking cannot be

[‡]The source code for our model is available at <https://github.com/kadarakos/IBMVisual>.

literal counts. We simply treat them as generalized, fractional feature “counts”. The end result is that given the lists of words in the image descriptions and the corresponding image vectors the model learns a probability distribution $t(f|w)$ over feature-vector indexes f for every word w in the descriptions.

18: end for

```

This is our sentence-vector alignment model, VISUAL. In the interest of cognitive plausibility, we train it using a single-pass, online algorithm. Algorithm 1 shows the pseudo-code. Our input is a sequence of pairs of D -dimensional feature vectors and sentences, and

the output is a translation table $t(f|w)$. We maintain two count tables of expected counts $a[f, w]$ and $a[\cdot, w]$ which are used to incrementally recompute the translation probabilities $t(f|w)$. The initial translation probabilities are uniform (line 7). In lines 12-14 the count tables are updated, based on translation probabilities weighted by the feature value $V[f]$, and normalized over all the words in the sentence. In line 15 the translation table is in turn updated.

Baseline models

To asses the quality of the meaning representations learned by our sentence-vector alignment model VISUAL, we compare its performance in a set of tasks to the following baselines:

- MONOLING: instead of aligning each sentence with its corresponding visual vector, this variation aligns two copies of each sentence with each other, and thus learns word representations based on word-word co-occurrences[§].
- WORD2VEC: for comparison we also report results with the skip-gram embedding model, also known as WORD2VEC which builds word representations based on word-word co-occurrences as well Mikolov et al. (2013a,b). WORD2VEC learns a vector representation (embedding) of a word which maximizes performance on predicting words in a small window around it.

[§]This model does not estimate probabilities of translation of a word to itself, that is probabilities of the form $t(w|w)$.

Experiments

Image datasets

We use image-caption datasets for our experiments. F8k Rashtchian et al. (2010) consists of 8000 images and five captions for each image. F30k Young et al. (2014) extends the F8k and contains 31,783 images with five captions each summing up to 158,915 sentences. For both data sets we use the splits from (Karpathy et al., 2014), leaving out 1000 images for validation and 1000 for testing from each set. Table 3.1 summarizes the statistics of the Flickr image-caption datasets.

	F8k	F30k
Train images	6,000	29,780
Validation images	1,000	1,000
Test images	1,000	1,000
Image in total	8,000	31,780
Captions per image	5	5
Captions in total	40,000	158,900

Table 3.1: *Flickr image caption datasets.*

For the Single-concept image descriptions experiments reported in section 3.3.4, we also use the ILSVRC2012 subset of ImageNet Russakovsky et al. (2014), a widely-used data set in the computer vision community. It is an image database that annotates the WordNet noun synset hierarchy with images. It contains 500 images per synset on average.

Word similarity experiments

A common evaluation task for assessing the quality of learned semantic vectors for words is measuring word similarity. A number of experiments have elicited human ratings on the similarity and/or relatedness of a list of word pairs. For instance one of the data sets we used was the SimLex999 data set, which contains similarity judgments for 666 noun pairs (organ-liver 6.15), 222 verb pairs (occur-happen 1.38) and 111 adjective pairs (nice-cruel 0.67) elicited by 500 participants recruited from Mechanical Turk. These types of data sets are commonly used as benchmarks for models of distributional semantics, where the learned representations are expected to show a significant positive correlation with human similarity judgments on a large number of word pairs.

We selected a subset of the existing benchmarks according to the size of their word pairs that overlap with our restricted vocabulary. We ran a statistical power analysis test to estimate the minimum number of required word pairs needed in our experiments. The projected sample size was $N = 210$ with $p = .05$, effect-size $r = .2$ and $power = 0.9$. Thus some of the well-known benchmarks were excluded due to their small sample size after we excluded words not present in our datasets.[¶]

The four standard benchmarks that contain the minimum number of word pairs are: the full WS-353 Finkelstein et al. (2001a), MTurk-771 Radinsky et al. (2011), MEN Bruni et al. (2014) and SimLex999 Hill et al. (2014). Note that the MTurk dataset only contains similarity judgments for nouns. Also, a portion of the full WordSim-353

[¶]These include RG-65 Rubenstein & Goodenough (1965), MC-30 Miller & Charles (1991) and YP-130 Yang & Powers (2006).

dataset reports relatedness ratings instead of word similarity.

Effect of concreteness on similarity judgments

The word similarity judgments provide a macro evaluation about the overall quality of the learned word representations. For more fine-grained analysis we turn to the dichotomy of concrete (e.g. *chair*, *car*) versus abstract (e.g. *love*, *sorrow*) nouns. Evidence presented by (Recchia & Jones, 2012) shows that in naming and lexical decision tasks the early activation of abstract concepts is facilitated by rich linguistic contexts, while physical contexts promote the activation of concrete concepts. Based on these recent findings, (Bruni et al., 2014) suggest that in case of computational models *concrete* words (such as names for physical objects and visual properties) are easier to learn from perceptual/visual input and *abstract* words are mainly learned based on their co-occurrence with other words in text. Following (Bruni et al., 2014), but using novel methodology, we also test this idea and examine whether more concrete words benefit more from visual features compared with less concrete ones.

In their work (Bruni et al., 2014) use the automatic method from (Turney et al., 2011) to assign concreteness values to words and split the MEN corpus in concrete and abstract chunks. From their experiments they draw the conclusion that visual information boosts their models' performance on concrete nouns. However, whereas the multi-modal embeddings of (Bruni et al., 2014) are trained using an unbalanced corpus of large quantities of textual information and far poorer visual stimuli, our visual embeddings are learned on a parallel corpus of sentences paired with images. To our purposes, this balance in the sources of information is critical as we aim at model-

ing word learning in humans. As a consequence of this setting we rather hypothesized that solely relying on visual features would result in better performance on more concrete words than on abstract ones and conversely, learning language solely from textual features would lead to higher correlations on the more abstract portion of the vocabulary.

To test this hypothesis, MEN, MTurk and Simlex999 datasets were split in two halves based on concreteness score of the word pairs. The "abstract" and "concrete" subclasses for each data set are obtained by ordering the pairs according to their concreteness and then partition the ordered tuples in halves. We defined the concreteness of a word pair as the product of the concreteness scores of the two words. The scores are taken from the University of South Florida Free Association Norms dataset Nelson et al. (1998). Table 3.2 provides an overview of the benchmarks we use in this study. Column "Concreteness" shows the average concreteness scores of all words pairs per data set, while columns "Concrete" and "Abstract" contain the average concreteness of the concrete and abstract halves of the word-pairs respectively.

	#Pairs			Concreteness		
	Total	F8k	F30k	Full set	Concrete	Abstract
WS353	353	104	232	25.09	35.44	16.22
SimLex999	999	412	733	23.86	35.72	11.99
MEN	3000	2069	2839	29.77	36.28	23.26
MTurk771	771	295	594	25.89	34.02	16.16

Table 3.2: Summary of the word-similarity benchmarks, showing the number of word pairs in the benchmarks and the size of their overlap with the F8k and F30k data sets. The table also reports the average concreteness of the whole, concrete and abstract portions of the benchmarks.

Word production

Learning multi-modal word representations gives us the advantage of replicating real-life tasks such as naming visual entities. In this study, we simulate a word production task as follows: given an image from the test set, we rank all words in our vocabulary according to their cosine similarity to the visual vector representing the image. We evaluate these ranked lists in two different ways.

Multi-word image descriptions.

We use images from the test portion of the F8k and F30k datasets as benchmarks. These images are each labeled with up to five captions, or multi-word descriptions of the content of the image. To evaluate the performance of our model in producing words for each image, we construct the target description of an image as the union of the words in all its captions (with stop-words[¶] removed). We compare this set with the top N words in our predicted ranked word list. As a baseline for this experiment we implemented a simple frequency baseline **FREQ**, which for every image retrieves the top N most frequent words. The second model **COSINE** uses our **VISUAL** word-embeddings and ranks the words based on their cosine similarity to the given image. The final model **PRIOR** implements a probabilistic interpretation of the task

$$P(w_i|i_j) \propto P(i_j|w_i) \times P(w_i), \quad (3.1)$$

where w_i is a word from the vocabulary of the captions and i_j

[¶]Function words such as *the*, *is*, *at*, *what*, *there*; we used the stop-word list from the Python library NLTK.

is an image from the collections of images I . The probability of an image given a word is defined as

$$P(i_j|w_i) = \frac{\text{cosine}(i_j, w_i)}{\sum_{k=1}^{|I|} \text{cosine}(i_k, w_i)}, \quad (3.2)$$

where $\text{cosine}(i_j, w_i)$ is the cosine between the vectorial representation of i_j and the VISUAL word-embedding w_i . Since in any natural language corpus the distribution of word frequencies is expected to be very heavy tailed, in the model PRIOR, rather than using maximum likelihood estimation, we reduce the importance of the differences in word-frequencies and smooth the prior probability $P(w_i)$ as described by equation 3.3, where N is the number of words in the vocabulary.

$$P(w_i) = \frac{\log(\text{count}(w_i))}{\sum_{j=1}^N \log(\text{count}(w_j))} \quad (3.3)$$

As a measure of performance, we report Precision at 5 (P@5) between the ranked word list and the target descriptions; i.e., proportion of correct target words among the top 5 predicted ranked words. Figure 3.2 shows an example of an image and its multi-word captions in the validation portion of the F30k dataset.

Single-concept image descriptions

Even though we use separate portions of F8k and F30k for training and testing, these subsets are still very similar. To test how general the VISUAL word representations are, we use images from the ILSVRC2012 subset of ImageNet Russakovsky et al. (2014) as benchmark. The major difference between these images and the ones from F8k and F30k datasets is that labels of the images in ImageNet are

A boy in a blue shirt and white helmet is riding a white bike

A boy in blue is riding his bike in a skate park

A boy on a BMX bike

A cyclist riding on their front wheel on the asphalt

The man is on a black and white bike

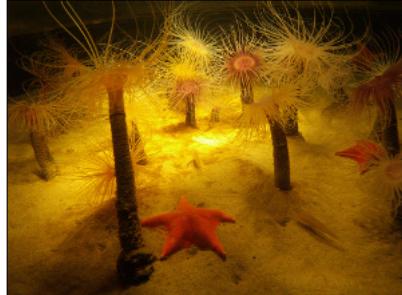

Descriptors: blue boy skate shirt asphalt helmet
park cyclist black bike wheel front
riding white bmx man

Predicted: bike bicycle riding man biker

Overlap: riding bike man

P@5: 0.6

Figure 3.2: Multiword image description example. Below the image are the 5 captions describing the image, the union of words that we take as targets, the top 5 predicted and the list of correct words and the P@5 score for the given test case.

Label: sea anemone anemone
Hypernym: animal

Figure 3.3: Example of the Single-concept image description task from the validation portion of the ILSVRC2012 subset of ImageNet. The terms "sea anemone" and "anemone" are unknown to VISUAL and "animal" is the first word among its hypernyms that appear in the vocabulary of F30k.

synsets from WordNet, which identify a single concept present in the image instead of providing a natural descriptions of its full content. Providing a quantitative evaluation in this case is not straightforward for two main reasons. First, the vocabulary of our model is restricted and the synsets in the ImageNet dataset are quite varied. Second, the synset labels can be very precise, much more so than the descriptions provided in the captions that we use as our training data.

To attempt to solve the vocabulary mismatch problem, we use synset hypernyms from WordNet as substitute target descriptors. If none of the lemmas in the target synset are in the vocabulary of the model, the lemmas in the hypernym synset are taken as new targets, until we reach the root of the taxonomy. However, we find that in a large number of cases these hypernyms are unrealistically general given the image. Figure 3.3 illustrates these issues.

Results

We evaluate our model on two main tasks: simulating human judgments of word similarity^{**} and producing labels for images. For all performance measures in this sections (Spearman’s ρ , P@5), we estimated the confidence intervals using the Bias-corrected Accelerated bootstrapping method^{††} Efron (1982).

Word similarity

We simulate the word similarity judgment task using the induced word vectors by three models: VISUAL, MONOLING, and WORD2VEC. All models were trained on the tokenized training portion of the F30k data set. While VISUAL is presented with pairs of captions and the 4,096 dimensional image-vectors, MONOLING and WORD2VEC^{‡‡} are trained solely on the sentences in the captions. The smoothing coefficient $\epsilon = 1.0$ was used for VISUAL and MONOLING. The WORD2VEC model was run for one iteration with default parameters, except for the minimum word count (as our models also consider each word in each sentence): feature-vector-size=100, alpha=0.025, window-size=5, min-count=5, downsampling=False, alpha=0.0001, model=skip-gram, hierarchical-sampling=True, negative-sampling=False.

Figure 3.4 illustrates the correlation of the similarity judgments by the three models with those of humans on four datasets. Table 3.3

^{**}We made available the source code used for running word similarity/relatedness experiments on https://bitbucket.org/kadar_akos/wordsims.

^{††}Provided by the scikits-bootstrap Python package <https://github.com/cgevans/scikits-bootstrap>.

^{‡‡}We used the Word2Vec implementation from the gensim Python package available at <https://radimrehurek.com/gensim/models/word2vec.html>.

shows the results in full detail: it reports the Spearman rank-order correlation coefficient between the human similarity judgments and the pairwise cosine similarities of the word vectors per data set along with the confidence intervals estimated by using bootstrap (the correlation values marked by a * were significant at level $p < 0.05$).

Although VISUAL achieves a higher correlation than the other two models on all datasets, the overlapping confidence intervals suggest that, in this particular setting, both VISUAL and WORD2VEC perform very similarly in approximating human similarity judgments. This result is particularly interesting as these models exploit different sources of information: The input to WORD2VEC is text only (i.e., the set of captions) and it learns from word-word co-occurrences, while VISUAL takes pairs of image vectors and sentences as input, and thus learns from word-scene co-occurrences.

The significant medium-sized correlation ($p < .001$, $\rho = 0.47$ 95% CI [0.44, 0.50]) with reasonably narrow confidence intervals on the large number of samples, $N = 2,839$, of the MEN data set supports the hypothesis that the similarities between the meaning representations learned by VISUAL mirror the distance between word pairs as estimated by humans. This result suggests that it is feasible to learn word meanings from co-occurrences of sentences with noisy visual scenes. However, on all other data sets, the effect sizes for all models are small and their performances vary considerably given different subsamples of the benchmarks.

Concreteness

Based on the previous findings of (Bruni et al., 2014), we expected that models relying on perceptual cues perform better on the concrete

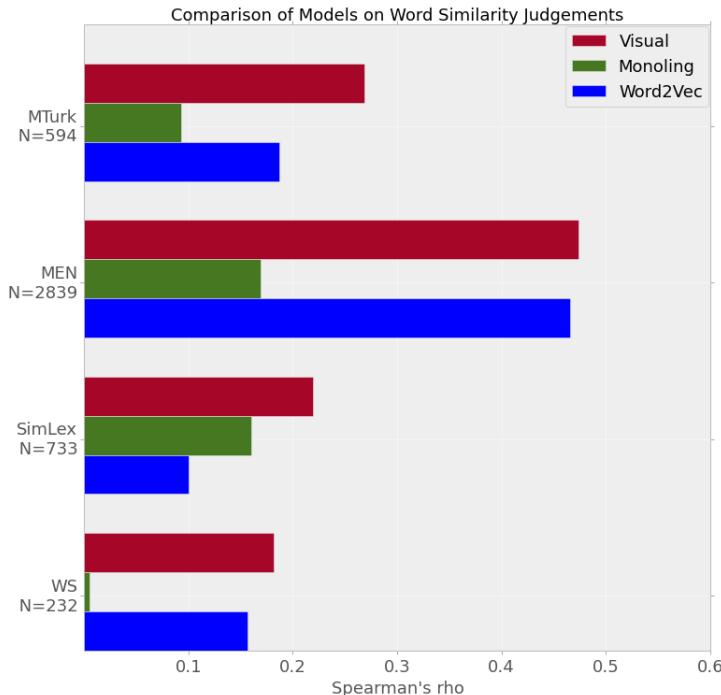

Figure 3.4: Comparison of models on approximating word similarity judgments. The length of the bars indicate the size of the correlation measured by Spearman's ρ , longer bars indicate better similarity between the models' predictions and the human data. The labels on the y-axis contain the names of the data sets and indicate the number of overlapping word pairs with the vocabulary of the F30k data set. All models were trained on the training portion of the F30k data set.

	WS	SimLex	MEN	MTurk
VISUAL	0.18* CI[0.05, 0.32]	0.22* CI[0.15, 0.29]	0.47* CI[0.44, 0.50]	0.27* CI[0.19, 0.34]
	0.08 CI[-0.06, 0.21]	0.18* CI[0.11, 0.25]	0.23* CI[0.19, 0.26]	0.17* CI[0.04, 0.19]
WORD2VEC	0.16* CI[0.02, 0.28]	0.10* CI[0.02, 0.17]	0.47* CI[0.43, 0.49]	0.19* CI[0.11, 0.26]

Table 3.3: Word similarity correlations with human judgments measured by Spearman’s ρ . Models were trained on the training portion of the F30k data set. The * next to the values marks the significance of the correlation at level $p < 0.05$. The confidence intervals for the correlation are estimated using bootstrap.

portion of the word-pairs in the word-similarity benchmarks. Furthermore, we expected approximating human word similarity judgments on concrete word-pairs to be generally easier. As discussed in section 3.3.3, we split the data sets into *abstract* and *concrete* halves and ran the word similarity experiments on the resulting portions of the word-pairs for comparison. Table 3.4 only reports the results on MEN and Simlex999 as these were the only benchmarks that had at least 200 word-pairs after partitioning. Table 3.2 summarizes the average concreteness of the different portions of the data sets.

On all data sets, VISUAL seems to perform considerably better on the concrete word-pairs than on abstract ones. On the abstract half of the MEN data set, the performance of VISUAL is $\rho = 0.35$, 95% $CI[0.29, 0.41]$, while it is $\rho = 0.56$, 95% $CI[0.49, 0.59]$ on the concrete portion. The non-overlapping confidence intervals support the hypothesis that VISUAL does significantly better on the concrete word pairs. This pattern, however, is not observed for WORD2VEC as there is no significant difference in its performance given the different concreteness levels of the word pairs. Splitting the word pairs in two

	MEN		SimLex	
	Abstract	Concrete	Abstract	Concrete
Visual	0.35* CI[0.29, 0.41]	0.55* CI[0.49, 0.59]	0.16* CI[0.04, 0.25]	0.39* CI[0.28, 0.47]
Word2Vec	0.48 CI[0.43, 0.53]	0.45 CI[0.39, 0.50]	0.14 CI[0.02, 0.25]	0.18 CI[0.07, 0.29]

Table 3.4: The table reports the Spearman rank-order correlation coefficient on the abstract and concrete portions of the data sets separately as well as the confidence intervals around the effect-sizes estimated by using bootstrap. The * next to the values indicates significance at level $p < 0.05$.

groups based on their concreteness scores reveals that performance of VISUAL is affected by concreteness and that it only performs better than WORD2VEC on the more concrete word pairs. Another pattern that the analysis reveals is that the average concreteness of the data sets is reflected in the performance of the models: for both VISUAL and WORD2VEC the rank of their performance follows the rank of concreteness of the benchmarks.

Word production

In this set of experiments, we evaluate the word meaning vectors learned by VISUAL by simulating the task of word production for an image, as described in Section 3.3.4. These experiments can be viewed as computational simulations of a language task where human subjects associate words to given images. Words were ranked according to their cosine similarity to a given image vector. The VISUAL model was trained on the training portion of the F8k and F30k data sets. We report results on two variations of the word production task: multi-word image descriptors, and single-concept image descriptors.

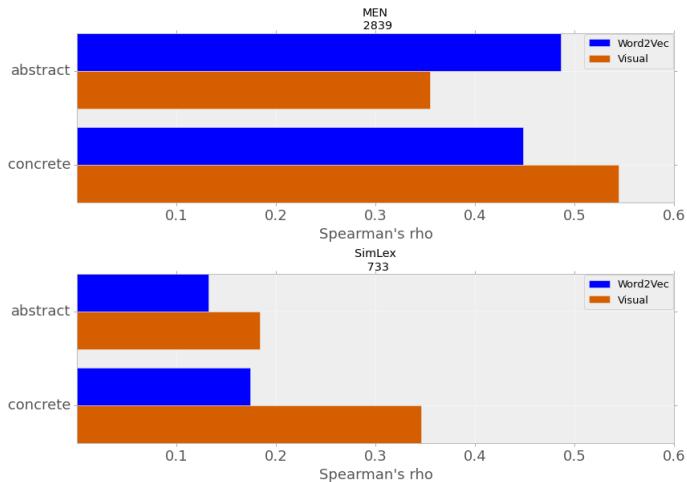

Figure 3.5: Models' performance on word similarity judgments as a function of the concreteness of the word pairs.

Multi-word image descriptors

The objective of the model in this experiment is to rank only words in the top N that occur in the set containing all words from the concatenation of the 5 captions of a given image with stop-words removed. The ranking models used for these experiments (FREQ, COSINE, and PRIOR) are described in section 3.3.4. Table 3.5 reports the results of the experiments on the respective test portions of the F8k and F30k datasets as estimated by P@5. We estimated the variability of the models' performance by calculating these measures per sample and estimating the confidence intervals around the means using bootstrap.

On these particular data sets the naive frequency baseline can perform particularly well: by only retrieving the sequence *wearing, woman, people, shirt, blue* the ranking model FREQ scores a P@5=.27

on F30k. Incorporating both the meaning representations learned by VISUAL and the prior probabilities of the words, the non-overlapping confidence intervals suggest that PRIOR significantly outperforms FREQ — $P@5=0.42$, 95% $CI[0.41, 0.44]$.

In addition to $P@5$, we also report the number of word types that were retrieved correctly given the images (column Words@5 on table 3.5). This measure was inspired by the observation that by focusing only on the precision scores it seems like incorporating visual information rather than just using raw word-frequency statistics provides a significant, but small advantage. However, taking into consideration that PRIOR retrieves 178 word types correctly suggests that it can retrieve less generic words that are especially descriptive of fewer scenes.

To have a more intuitive grasp on the performance of PRIOR, it is worth taking also into consideration the distribution of $P@5$ scores over the test cases. When trained and tested on F30k in most cases (34%), PRIOR retrieves two words correctly in the top 5 and in 23% and 25% of the cases it retrieves one and three respectively. In only 6% of the time $P@5 = 0$, which means that it is very unlikely that PRIOR named unrelated concepts given an image. These results suggest that VISUAL learns word meanings that allow for labeling unseen images with reasonable accuracy using a large variety of words.

Single-concept image descriptors

The motivation for this experiment was to assess the generalizability of the word-representations learned by VISUAL. Similarly to the previous task, the goal here is to associate words to a given image, but in this case the images are drawn from the validation set of

	F8k		F30k	
	P@5	Words@5	P@5	Words@5
FREQ	0.20 CI[0.19, 0.21]	5	0.27 CI[0.26, 0.29]	5
COSINE	0.16 CI[0.15, 0.17]	310	0.14 CI[0.13, 0.15]	371
PRIOR	0.44 CI[0.42, 0.45]	135	0.42 CI[0.41, 0.44]	178

Table 3.5: Results for the multi-word image descriptors experiments reported on the test sets of F8k and F30k. Words@5 the number of correctly retrieved word types in the top 5. The confidence intervals below P@5 scores were estimated using bootstrap.

ILSVRC2012 portion of ImageNet Russakovsky et al. (2014). Providing quantitative results is not as straightforward as in the case of multi-word image descriptors, since these images are not labeled with target descriptions, but with a synset from WordNet. As demonstrated in Figure 3.6, some of the lemmas in the target synsets are far too specific or unnatural for our purposes, for example *schooner* for an image depicting a sailboat or *alp* for an image of a mountain. In other cases, a particular object is named which might not be the most salient one, for example *freight car* for a picture of a graffiti with three pine trees on the side of railway carriage.

We made an attempt to search through the lemmas in the hypernym paths of the synsets until a known target lemma is reached. However, as demonstrated by examples in Figure 3.6, these hypernyms are often very general (e.g. *device*) and predicting such high-level concepts as descriptors of the image is unrealistic. In other cases, the lemmas from the hypernym synsets are simply misleading; for example, *wood* for describing a wooden wind instrument. As can

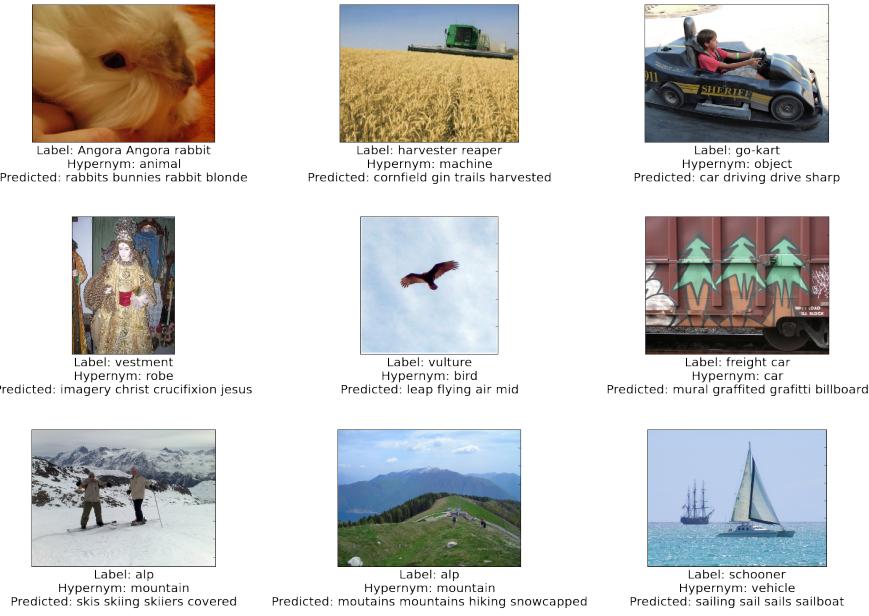

Figure 3.6: The caption above the images show the target labels, the hypernyms that were considered as a new target if the original was not in the vocabulary and the top N predicted words. In a large number of cases the guesses of the model are conceptually similar to the images, although, do not actually overlap with the labels or the hypernyms.

be seen in the examples in Figure 3.6, the top ranked words predicted by our model are in fact conceptually more similar to the images covering a variety of objects and concepts than the labels specified in the dataset.

We conclude that in the future, to quantitatively investigate the cognitive plausibility of cross-situational models of word learning, the collection of feature production norms for ImageNet Russakovsky et al. (2014) would be largely beneficial.

Discussion and conclusion

We have presented a computational cross-situational word learning model that learns word meanings from pairs images and their natural language descriptions. Unlike previous word learning studies which often rely on artificially generated perceptual input, the visual features we extract from images of natural scenes offers a more realistic simulation of the cognitive tasks humans face, since our data includes a significant level of ambiguity and referential uncertainty.

Our results suggest that the proposed model can learn meaningful representations for individual words from varied scenes and their multiword descriptions. Learning takes place incrementally and without assuming access to single-word unambiguous utterances or corrective feedback. When using the learned visual vector representations for simulating human ratings of word-pair similarity, our model shows significant correlation with human similarity judgments on a number of benchmarks. Moreover, it moderately outperforms other models that only rely on word-word co-occurrence statistics to learn word meaning.

The comparable performance of visual versus word-based models seems to be in line with (Louwerse, 2011), who argues that linguistic and perceptual information show a strong correlation, and therefore meaning representations solely based on linguistic data are not distinguishable from representations learned from perceptual information. However, an analysis of the impact of word concreteness on the performance of our model shows that visual features are especially useful when estimating the similarity of more concrete word pairs. In contrast, models that rely on word-based cues do not show such improvement when judging the similarity of concrete word pairs. These

results suggest that these two sources of information might best be viewed as complementary, as also argued by (Bruni et al., 2014).

We also used the word meaning representations that our model learns from visual input to predict the best label for a given image. This task is similar to word production in language learners. Our quantitative and qualitative analyses show that the learned representations are informative and the model can produce intuitive labels for the images in our dataset. However, as discussed in the previous section, the available image collections and their labels are not developed to suit our purpose, as most of the ImageNet labels are too detailed and at a taxonomic level which is not compatible with how language learners name a visual concept.

Finally, a natural next step for this model is to also take into account cues from sentence structure. For example, (Alishahi & Chrupała, 2012) try to include basic syntactic structure by introducing a separate category learning module into their model. Alternatively, learning sequential structure and visual features could be modeled in an integrated rather than modular fashion, as done by the multimodal captioning systems based on recurrent neural nets (see section 3.1.2). We are currently developing this style of integrated model to investigate the impact of structure on word learning from a cognitive point of view.

4

Representation of linguistic form and function in recurrent neural networks

abstract We present novel methods for analyzing the activation patterns of RNNs from a linguistic point of view and explore the types of linguistic structure they learn. As a case study, we use a standard standalone language model, and a multi-task gated recurrent network architecture consisting of two parallel pathways with shared word embeddings; The VISUAL pathway is trained on predicting the representations of the visual scene corresponding to an input sentence, whereas the TEXTUAL pathway is trained to predict the next word in the same sentence. We propose a method for estimating the amount of contribution of individual tokens in the input to

the final prediction of the networks. Using this method, we show that the VISUAL pathway pays selective attention to lexical categories and grammatical functions that carry semantic information, and learns to treat word types differently depending on their grammatical function and their position in the sequential structure of the sentence. In contrast, the language models are comparatively more sensitive to words with a syntactic function. Further analysis of the most informative n-gram contexts for each model shows that in comparison to the VISUAL pathway, the language models react more strongly to abstract contexts that represent syntactic constructions.

Introduction

Recurrent neural networks (RNNs) were introduced by (Elman, 1990) as a connectionist architecture with the ability to model the temporal dimension. They have proved popular for modeling language data as they learn representations of words and larger linguistic units directly from the input data, without feature engineering. Variations of the RNN architecture have been applied in several NLP domains such as parsing Vinyals et al. (2015a) and machine translation Bahdanau et al. (2015a), as well as in computer vision applications such as image generation Gregor et al. (2015) and object segmentation Visin et al. (2016). RNNs are also important components of systems integrating vision and language, e.g. image Karpathy & Fei-Fei (2015) and video captioning Yu et al. (2015).

These networks can represent variable-length linguistic expressions by encoding them into a fixed-size low-dimensional vector. The nature and the role of the components of these representations are not directly interpretable as they are a complex, non-linear function

of the input. There have recently been numerous efforts to visualize deep models such as convolutional neural networks in the domain of computer vision, but much less so for variants of RNNs and for language processing.

The present paper develops novel methods for uncovering abstract linguistic knowledge encoded by the distributed representations of RNNs, with a specific focus on analyzing the hidden activation patterns rather than word embeddings and on the syntactic generalizations that models learn to capture. In the current work we apply our methods to a specific architecture trained on specific tasks, but also provide pointers about how to generalize the proposed analysis to other settings.

As our case study we picked the IMAGINET model introduced by (Chrupała et al., 2015a). It is a multi-task, multi-modal architecture consisting of two Gated-Recurrent Unit (GRU) Cho et al. (2014a); Chung et al. (2014) pathways and a shared word embedding matrix. One of the GRUs (VISUAL) is trained to predict image vectors given image descriptions, while the other pathway (TEXTUAL) is a language model, trained to sequentially predict each word in the descriptions. This particular architecture allows a comparative analysis of the hidden activation patterns between networks trained on two different tasks, while keeping the training data and the word embeddings fixed. Recurrent neural language models akin to TEXTUAL which are trained to predict the next symbol in a sequence are relatively well understood, and there have been some attempts to analyze their internal states (Elman, 1991; Karpathy et al., 2016, among others). In contrast, VISUAL maps a complete sequence of words to a representation of a corresponding visual scene and is a less

commonly encountered, but a more interesting model from the point of view of representing meaning conveyed via linguistic structure. For comparison, we also consider a standard standalone language model.

We report a thorough quantitative analysis to provide a linguistic interpretation of the networks' activation patterns. We present a series of experiments using a novel method we call *omission score* to measure the importance of input tokens to the final prediction of models that compute distributed representations of sentences. Furthermore, we introduce a more global measure for estimating the informativeness of various types of n-gram contexts for each model. These techniques can be applied to various RNN architectures, Recursive Neural Networks and Convolutional Neural Networks.

Our experiments show that the VISUAL pathway in general pays special attention to syntactic categories which carry semantic content, and particularly to nouns. More surprisingly, this pathway also learns to treat word types differently depending on their grammatical function and their position in the sequential structure of the sentence. In contrast, the TEXTUAL pathway and the standalone language model are especially sensitive to the local syntactic characteristics of the input sentences. Further analysis of the most informative n-gram contexts for each model shows that while the VISUAL pathway is mostly sensitive to lexical (i.e., token n-gram) contexts, the language models react more strongly to abstract contexts (i.e., dependency relation n-grams) that represent syntactic constructions.

Related work

The direct predecessors of modern architectures were first proposed in the seminal paper of (Elman, 1990). He modifies the recurrent neural

network architecture of (Jordan, 1986) by changing the output-to-memory feedback connections to hidden-to-memory recurrence, enabling Elman networks to represent arbitrary dynamic systems. (Elman, 1991) trains an RNN on a small synthetic sentence dataset and analyzes the activation patterns of the hidden layer. His analysis shows that these distributed representations encode lexical categories, grammatical relations and hierarchical constituent structures. (Giles et al., 1991) train RNNs similar to Elman networks on strings generated by small deterministic regular grammars with the objective to recognize grammatical and reject ungrammatical strings, and develop the *dynamic state partitioning* technique to extract the learned grammar from the networks in the form of deterministic finite state automatons.

More closely related is the recent work of (Li et al., 2016a), who develop techniques for a deeper understanding of the activation patterns of RNNs, but focus on models with modern architectures trained on large scale data sets. More specifically, they train Long Short-Term Memory networks (LSTM) Hochreiter & Schmidhuber (1997) for phrase-level sentiment analysis and present novel methods to explore the inner workings of RNNs. They measure the salience of tokens in sentences by taking the first-order derivatives of the loss with respect to the word embeddings and provide evidence that LSTMs can learn to attend to important tokens in sentences. Furthermore, they plot the activation values of hidden units through time using heat maps and visualize local semantic compositionality in RNNs. In comparison, the present work goes beyond the importance of single words and focuses more on exploring structure learning in RNNs, as well as on developing methods for a comparative analysis between

RNNs that are focused on different modalities (language versus vision).

Adding an explicit attention mechanism that allows the RNNs to focus on different parts of the input was recently introduced by (Bahdanau et al., 2015a) in the context of extending the sequence-to-sequence RNN architecture for neural machine translation. At the decoding side this neural module assigns weights to the hidden states of the decoder, which allows the decoder to selectively pay varying degrees of attention to different phrases in the source sentence at different decoding time-steps. They also provide qualitative analysis by visualizing the attention weights and exploring the importance of the source encodings at various decoding steps. Similarly (Rocktäschel et al., 2016) use an attentive neural network architecture to perform natural language inference and visualize which parts of the hypotheses and premises the model pays attention to when deciding on the entailment relationship. Conversely, the present work focuses on RNNs without an explicit attention mechanism.

(Karpathy et al., 2016) also take up the challenge of rendering RNN activation patterns understandable, but use character level language models and rather than taking a linguistic point of view, focus on error analysis and training dynamics of LSTMs and GRUs. They show that certain dimensions in the RNN hidden activation vectors have specific and interpretable functions. Similarly, (Li et al., 2016d) use a Convolutional Neural Networks (CNN) based on the architecture of (Krizhevsky et al., 2012), and train it on the ImageNet dataset using different random initializations. For each layer in all networks they store the activation values produced on the validation set of ILSVRC and align similar neurons of different networks. They con-

clude that while some features are learned across networks, some seem to depend on the initialization. Other works on visualizing the role of individual hidden units in deep models for vision synthesize images by optimizing random images through backpropagation to maximize the activity of units Erhan et al. (2009); Simonyan et al. (2013); Yosinski et al. (2015); Nguyen et al. (2016) or to approximate the activation vectors of particular layers Mahendran & Vedaldi (2016); Dosovitskiy & Brox (2015).

While this paper was under review, a number of articles appeared which also investigate linguistic representations in LSTM architectures. In an approach similar to ours, (Li et al., 2016b) study the contribution of individual input tokens as well as hidden units and word embedding dimensions by erasing them from the representation and analyzing how this affects the model. They focus on text-only tasks and do not take other modalities such as visual input into account. (Adi et al., 2017) take an alternative approach by introducing prediction tasks to analyze information encoded in sentence embeddings about sentence length, sentence content and word order. Finally, (Linzen et al., 2016) examine the acquisition of long-distance dependencies through the study of number agreement in different variations of an LSTM model with different objectives (number prediction, grammaticality judgment, and language modeling). Their results show that such dependencies can be captured with very high accuracy when the model receives a strong supervision signal (that is, whether the subject is plural or singular), but simple language models still capture the majority of test cases. While they focus on an in-depth analysis of a single phenomenon, in our work we are interested in methods which make it possible to uncover a broad variety

of patterns of behavior in RNNs.

In general, there has been a growing interest within computer vision in understanding deep models, with a number of papers dedicated to visualizing learned CNN filters and pixel saliences Simonyan et al. (2013); Yosinski et al. (2015); Mahendran & Vedaldi (2015). These techniques have also led to improvements in model performance Eigen et al. (2014) and transferability of features Zhou et al. (2015). To date there has been much less work on such issues within computational linguistics. We aim to fill this gap by adapting existing methods as well as developing novel techniques to explore the linguistic structure learned by recurrent networks.

Models

In our analyses of the acquired linguist knowledge, we apply our methods to the following models:

- IMAGINET: A multi-modal Gated Recurrent Unit (GRU) network consisting of two pathways, VISUAL and TEXTUAL, coupled via word embeddings.
- LM: A (unimodal) language model consisting of a GRU network.
- SUM: A network with the same objective as the VISUAL pathway of IMAGINET, but which uses sum of word embeddings instead of a GRU.

The rest of this section gives a detailed description of these models.

Gated Recurrent Neural Networks

One of the main difficulties for training traditional Elman networks arises from the fact that they overwrite their hidden states at every time step with a new value computed from the current input \mathbf{x}_t and the previous hidden state \mathbf{h}_{t-1} . Similarly to LSTMs, Gated Recurrent Unit networks introduce a mechanism which facilitates the retention of information over multiple time steps. Specifically, the GRU computes the hidden state at current time step \mathbf{h}_t , as the linear combination of previous activation \mathbf{h}_{t-1} , and a new *candidate* activation $\tilde{\mathbf{h}}_t$:

$$\text{GRU}(\mathbf{h}_{t-1}, \mathbf{x}_t) = (1 - \mathbf{z}_t) \odot \mathbf{h}_{t-1} + \mathbf{z}_t \odot \tilde{\mathbf{h}}_t \quad (4.1)$$

where \odot is elementwise multiplication, and the update gate activation \mathbf{z}_t determines the amount of new information mixed in the current state:

$$\mathbf{z}_t = \sigma_s(\mathbf{W}_z \mathbf{x}_t + \mathbf{U}_z \mathbf{h}_{t-1}) \quad (4.2)$$

The candidate activation is computed as:

$$\tilde{\mathbf{h}}_t = \sigma(\mathbf{W} \mathbf{x}_t + \mathbf{U}(\mathbf{r}_t \odot \mathbf{h}_{t-1})) \quad (4.3)$$

The reset gate \mathbf{r}_t determines how much of the current input \mathbf{x}_t is mixed in the previous state \mathbf{h}_{t-1} to form the candidate activation:

$$\mathbf{r}_t = \sigma_s(\mathbf{W}_r \mathbf{x}_t + \mathbf{U}_r \mathbf{h}_{t-1}) \quad (4.4)$$

where \mathbf{W} , \mathbf{U} , \mathbf{W}_z , \mathbf{U}_z , \mathbf{W}_r and \mathbf{U}_r are learnable parameters.

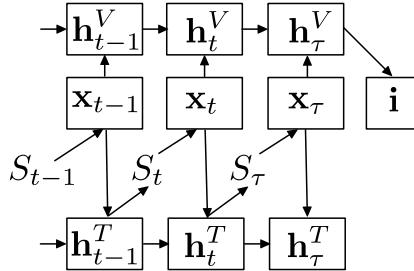

Figure 4.1: Structure of IMAGINET, adapted from Chrupała et al. (2015a).

Imaginet

IMAGINET introduced in (Chrupała et al., 2015a) is a multi-modal GRU network architecture that learns visually grounded meaning representations from textual and visual input. It acquires linguistic knowledge through language comprehension, by receiving a description of a scene and trying to visualise it through predicting a visual representation for the textual description, while concurrently predicting the next word in the sequence.

Figure 4.1 shows the structure of IMAGINET. As can be seen from the figure, the model consists of two GRU pathways, TEXTUAL and VISUAL, with a shared word embedding matrix. The inputs to the model are pairs of image descriptions and their corresponding images. The TEXTUAL pathway predicts the next word at each position in the sequence of words in each caption, whereas the VISUAL pathway predicts a visual representation of the image that depicts the scene described by the caption after the final word is received.

Formally, each sentence is mapped to two sequences of hidden states, one by VISUAL and the other by TEXTUAL:

$$\mathbf{h}_t^V = \text{GRU}^V(\mathbf{h}_{t-1}^V, \mathbf{x}_t) \quad (4.5)$$

$$\mathbf{h}_t^T = \text{GRU}^T(\mathbf{h}_{t-1}^T, \mathbf{x}_t) \quad (4.6)$$

At each time step TEXTUAL predicts the next word in the sentence S from its current hidden state \mathbf{h}_t^T , while VISUAL predicts the image-vector* $\hat{\mathbf{i}}$ from its last hidden representation \mathbf{h}_t^V .

$$\hat{\mathbf{i}} = \mathbf{V}\mathbf{h}_\tau^V \quad (4.7)$$

$$p(S_{t+1}|S_{1:t}) = \text{softmax}(\mathbf{L}\mathbf{h}_t^T) \quad (4.8)$$

The loss function is a multi-task objective which penalizes error on the visual and the textual targets simultaneously. The objective combines cross-entropy loss L^T for the word predictions and cosine distance L^V for the image predictions[†], weighting them with the parameter α (set to 0.1).

$$L^T(\theta) = -\frac{1}{\tau} \sum_{t=1}^{\tau} \log p(S_t|S_{1:t}) \quad (4.9)$$

$$L^V(\theta) = 1 - \frac{\hat{\mathbf{i}} \cdot \mathbf{i}}{\|\hat{\mathbf{i}}\| \|\mathbf{i}\|} \quad (4.10)$$

$$L = \alpha L^T + (1 - \alpha) L^V \quad (4.11)$$

For more details about the IMAGINET model and its performance

*Representing the full image, extracted from the pre-trained Convolutional Neural Network of (Simonyan & Zisserman, 2014).

[†]Note that the original formulation in (Chrupała et al., 2015a) uses mean squared error instead; as the performance of VISUAL is measured on image-retrieval which is based on cosine distances, we use cosine distance as the visual loss here.

see (Chrupała et al., 2015a). Note that we introduce a small change in the image representation: we observe that using standardized image vectors, where each dimension is transformed by subtracting the mean and dividing by standard deviation, improves performance.

Unimodal language model

The model LM is a language model analogous to the TEXTUAL pathway of IMAGINET with the difference that its word embeddings are not shared, and its loss function is the cross-entropy on word prediction. Using this model we remove the visual objective as a factor, as the model does not use the images corresponding to captions in any way.

Sum of word embeddings

The model SUM is a stripped-down version of the VISUAL pathway, which does not share word embeddings, only uses the cosine loss function, and replaces the GRU network with a summation over word embeddings. This removes the effect of word order from consideration. We use this model as a baseline in the sections which focus on language structure.

Experiments

In this section, we report a series of experiments in which we explore the kinds of linguistic regularities the networks learn from word-level input. In Section 4.4.1 we introduce *omission score*, a metric to measure the contribution of each token to the prediction of the networks, and in Section 4.4.2 we analyze how omission scores are dis-

tributed over dependency relations and part-of-speech categories. In Section 4.4.3 we investigate the extent to which the importance of words for the different networks depend on the words themselves, their sequential position, and their grammatical function in the sentences. Finally, in Section 4.4.4 we systematically compare the types of n-gram contexts that trigger individual dimensions in the hidden layers of the networks, and discuss their level of abstractness.

In all these experiments we report our findings based on the IMAGINET model, and whenever appropriate compare it to our two other models LM and SUM. For all the experiments, we trained the models on the training portion of the MSCOCO image-caption dataset Lin et al. (2014), and analyzed the representations of the sentences in the validation set corresponding to 5000 randomly chosen images. The target image representations were extracted from the pre-softmax layer of the 16-layer CNN of (Simonyan & Zisserman, 2014).

Computing Omission Scores

We propose a novel technique for interpreting the activation patterns of neural networks trained on language tasks from a linguistic point of view, and focus on the high-level understanding of what parts of the input sentence the networks pay most attention to. Furthermore, we investigate if the networks learn to assign different amounts of importance to tokens depending on their position and grammatical function in the sentences.

In all the models the full sentences are represented by the activation vector at the end-of-sentence symbol (\mathbf{h}_{end}). We measure the salience of each word S_i in an input sentence $S_{1:n}$ based on how much the representation of the partial sentence $S_{\setminus i} = S_{1:i-1}S_{i+1:n}$, with the

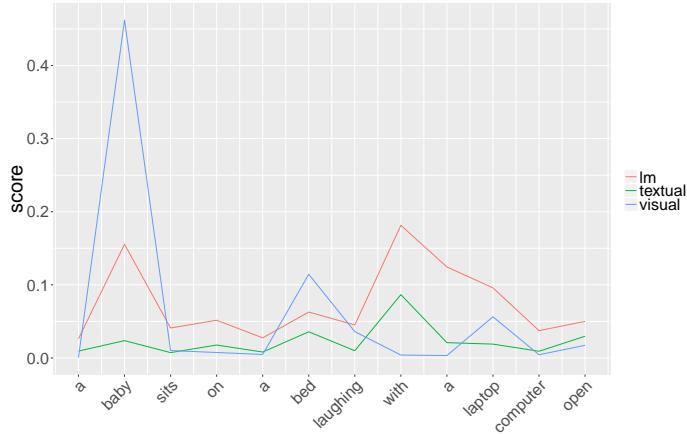

Figure 4.2: Omission scores for the example sentence *a baby sits on a bed laughing with a laptop computer open* for LM and the two pathways, TEXTUAL and VISUAL, of IMAGINET.

omitted word S_i , deviates from that of the original sentence representation. For example, the distance between $\mathbf{h}_{\text{end}}(\text{"the black dog is running"})$ and $\mathbf{h}_{\text{end}}(\text{"the dog is running"})$ determines the importance of *black* in the first sentence. We introduce the measure $\text{omission}(i, S)$ for estimating the salience of a word S_i :

$$\text{omission}(i, S) = 1 - \text{cosine}(\mathbf{h}_{\text{end}}(S), \mathbf{h}_{\text{end}}(S_{\setminus i})) \quad (4.12)$$

Figure 4.2 demonstrates the omission scores for the LM, VISUAL and TEXTUAL models for an example caption. Figure 4.3 shows the images retrieved by VISUAL for the full caption and for the one with the word *baby* omitted. The images are retrieved from the validation set of MS-COCO by: 1) computing the image representation of the

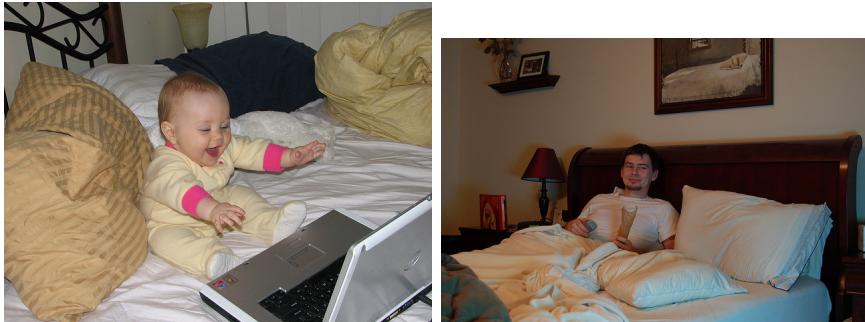

Figure 4.3: Images retrieved for the example sentence *a baby sits on a bed laughing with a laptop computer open* (left) and the same sentence with the second word omitted (right).

given sentence with VISUAL; 2) extracting the CNN features for the images from the set; and 3) finding the image that minimizes the cosine distance to the query. The omission scores for VISUAL show that the model paid attention mostly to *baby* and *bed* and slightly to *laptop*, and retrieved an image depicting a baby sitting on a bed with a laptop. Removing the word *baby* leads to an image that depicts an adult male laying on a bed. Figure 4.2 also shows that in contrast to VISUAL, TEXTUAL distributes its attention more evenly across time steps instead of focusing on the types of words related to the corresponding visual scene. The peaks for LM are the same as for TEXTUAL, but the variance of the omission scores is higher, suggesting that the unimodal language model is more sensitive overall to input perturbations than TEXTUAL.

Omission score distributions

The omission scores can be used not only to estimate the importance of individual words, but also of syntactic categories. We estimate

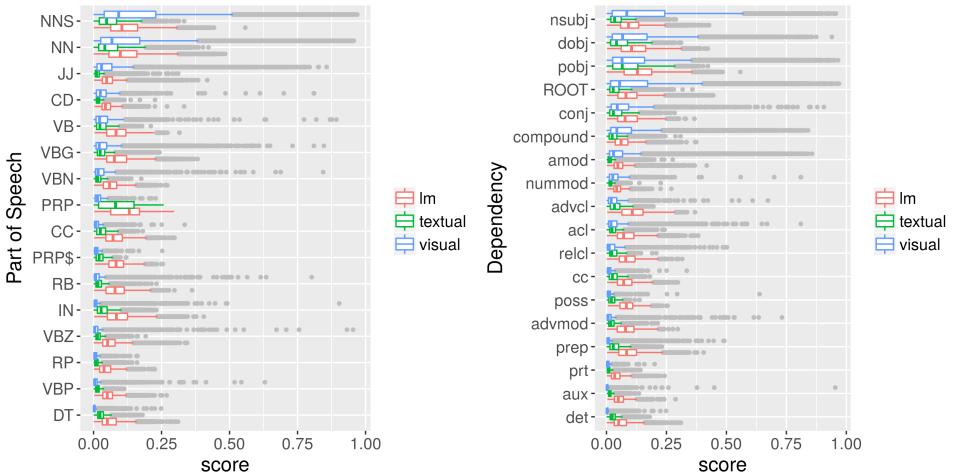

Figure 4.4: Distribution of omission scores for POS (left) and dependency labels (right), for the TEXTUAL and VISUAL pathways and for LM. Only labels which occur at least 1250 times are included.

the salience of each syntactic category by accumulating the omission scores for all words in that category. We tag every word in a sentence with the part-of-speech (POS) category and the dependency relation (deprel) label of its incoming arc. For example, for the sentence *the black dog*, we get (*the*, DT, det), (*black*, JJ, amod), (*dog*, NN, root). Both POS tagging and dependency parsing are performed using the `en_core_web_md` dependency parser from the Spacy package.[‡]

Figure 4.4 shows the distribution of omission scores per POS and dependency label for the two pathways of IMAGINET and for LM.[§]

[‡] Available at <https://spacy.io/>.

[§]The boxplots in this and subsequent figures are Tukey boxplots and should be interpreted as follows: the box extends from the 25th to the 75th percentile of the data; the line across the box is the 50th percentile, while the whiskers extend past the lower and upper quartile to $1.5 \times$ the interquartile range (i.e. 75th percentile - 25th percentile); the points are outliers.

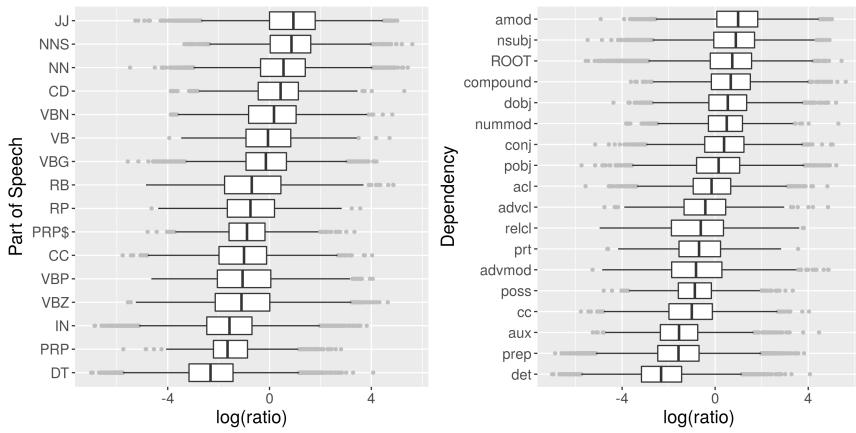

Figure 4.5: Distributions of log ratios of omission scores of TEXTUAL to VISUAL per POS (left) and dependency labels (right). Only labels which occur at least 1250 times are included.

The general trend is that for the VISUAL pathway, the omission scores are high for a small subset of labels - corresponding mostly to nouns, less so for adjectives and even less for verbs - and low for the rest (mostly function words and various types of verbs). For TEXTUAL the differences are smaller, and the pathway seems to be sensitive to the omission of most types of words. For LM the distribution over categories is also relatively uniform, but the omission scores are higher overall than for TEXTUAL.

Figure 4.5 compares the two pathways of IMAGINET directly using the log of the ratio of the VISUAL to TEXTUAL omission scores, and plots the distribution of this ratio for different POS and dependency labels. Log ratios above zero indicate stronger association with the VISUAL pathway and below zero with the TEXTUAL pathway. We see that in relative terms, VISUAL is more sensitive to adjectives (JJ), nouns (NNS, NN), numerals (CD) and participles (VBN), and

`TEXTUAL` to determiners (DT), pronouns (PRP), prepositions (IN) and finite verbs (VBZ, VBP).

This picture is complemented by the analysis of the relative importance of dependency relations: `VISUAL` pays most attention to the relations AMOD, NSUBJ, ROOT, COMPOUND, DOBJ, NUMMOD whereas `TEXTUAL` is more sensitive to DET, PREP, AUX, CC, POSS, ADVMOD, PRT, RELCL. As expected, `VISUAL` is more focused on grammatical functions typically filled by semantically contentful words, while `TEXTUAL` distributes its attention more uniformly and attends relatively more to purely grammatical functions.

It is worth noting, however, the relatively low omission scores for verbs in the case of `VISUAL`. One might expect that the task of image prediction from descriptions requires general language understanding and so high omission scores for all content words in general; however, the results suggest that this setting is not optimal for learning useful representations of verbs, which possibly leads to representations that are too task-specific and not transferable across tasks.

Figure 4.6 shows a similar analysis contrasting LM with the `TEXTUAL` pathway of IMAGINET. The first observation is that the range of values of the log ratios is narrow, indicating that the differences between these two networks regarding which grammatical categories they are sensitive to is less pronounced than when comparing `VISUAL` to `TEXTUAL`. While the size of the effect is weak, there also seems to be a tendency for the `TEXTUAL` model to pay relatively more attention to content and less to function words, compared to LM: it may be that the `VISUAL` pathway pulls `TEXTUAL` in this direction by sharing word embeddings with it.

Most of our findings up to this point conform reasonably well to

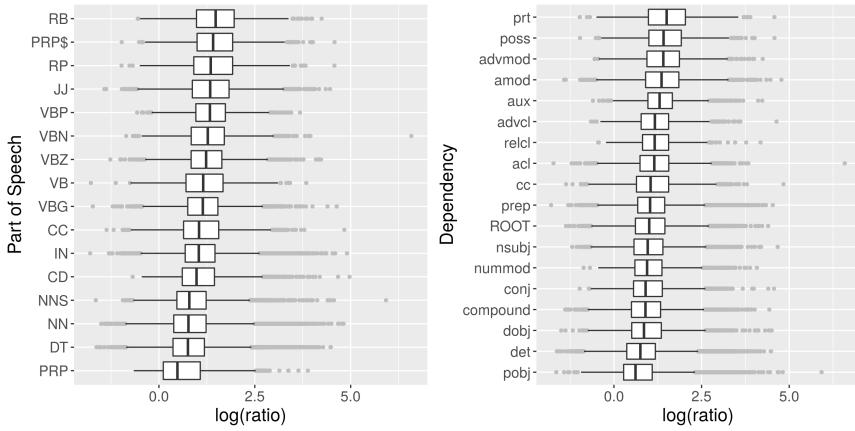

Figure 4.6: Distributions of log ratios of omission scores of LM to TEXTUAL per POS (left) and dependency labels (right). Only labels which occur at least 1250 times are included.

prior expectations about effects that particular learning objectives should have. This fact serves to validate our methods. In the next section we go on to investigate less straightforward patterns.

Beyond Lexical Cues

Models that utilize the sequential structure of language have the capacity to interpret the same word type differently depending on the context. The omission score distributions in Section 4.4.2 show that in the case of IMAGINET the pathways are differentially sensitive to content vs. function words. In principle, this may be either just due to purely lexical features or the model may actually learn to pay more attention to the same word type in appropriate contexts. This section investigates to what extent our models discriminate between occurrences of a given word in different positions and grammatical functions.

Table 4.1: Proportion of variance in omission scores explained by linear regression.

	word	+pos	+dep	full
SUM	0.654	0.661	0.670	0.670
LM	0.358	0.586	0.415	0.601
TEXTUAL	0.364	0.703	0.451	0.715
VISUAL	0.490	0.506	0.515	0.523

We fit four L2-penalized linear regression models which predict the omission scores per token with the following predictor variables:

1. LR WORD: word type
2. LR +DEP: word type, dependency label and their interaction
3. LR +POS: word type, position (binned as FIRST, SECOND, THIRD, MIDDLE, ANTEPENULT, PENULT, LAST) and their interaction
4. LR FULL: word type, dependency label, position, word:dependency interaction, word:position interaction

We use the 5000-image portion of MSCOCO validation data for training and test. The captions contain about 260,000 words in total, of which we use 100,000 to fit the regression models. We then use the rest of the words to compute the proportion of variance explained by the models. For comparison we also use the SUM model which composes word embeddings via summation, and uses the same loss function as VISUAL. This model is unable to encode information about word order, and thus is a good baseline here as we investigate the sensitivity of the networks to positional and structural cues.

Table 4.1 shows the proportion of variance R^2 in omission scores explained by the linear regression with the different predictors. The raw R^2 scores show that for the language models LM and TEXTUAL, the word type predicts the omission-score to much smaller degree compared to VISUAL. Moreover, adding information about either the position or the dependency labels increases the explained variance for all models. However, for the TEXTUAL and LM models the position of the word adds considerable amount of information. This is not surprising considering that the omission scores are measured with respect to the final activation state, and given the fact that in a language model the recent history is most important for accurate prediction.

Figure 4.7 offers a different view of the data, showing the increase or decrease in R^2 for the models relative to LR +POS to emphasise the importance of syntactic structure beyond the position in the sentence. Interestingly, for the VISUAL model, dependency labels are more informative than linear position, hinting at the importance of syntactic structure beyond linear order. There is a sizeable increase in R^2 between LR +POS and LR FULL in the case of VISUAL, suggesting that the omission scores for VISUAL depend on the words' grammatical function in sentences, *even after controlling for word identity and linear position*. In contrast, adding additional information on top of lexical features in the case of SUM increases the explained variance only slightly, which is most likely due to the unseen words in the held out set.

Overall, when regressing on word identities, word position and dependency labels, the VISUAL model's omission scores are the hardest to predict of the four models. This suggests that VISUAL may

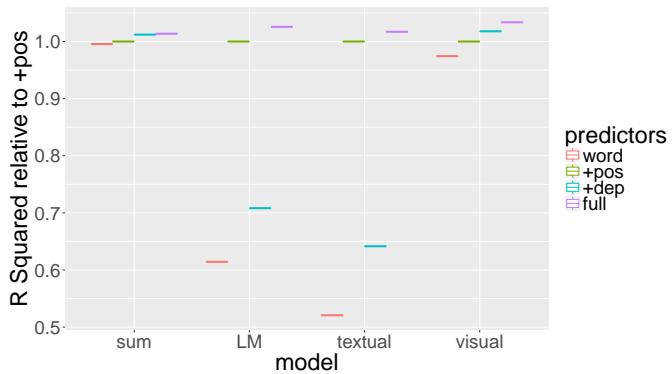

Figure 4.7: Proportion of variance in omission scores explained by the linear regression models for SUM, LM, VISUAL and TEXTUAL, relative to regressing on word identity and position only.

be encoding additional structural features not captured by these predictors. We will look more deeply into such potential features in the following sections.

Sensitivity to grammatical function

In order to find out some of the specific syntactic configurations leading to an increase in R^2 between the LR WORD and LR +DEP predictors in the case of VISUAL, we next considered all word types with occurrence counts of at least 100 and ranked them according to how much better, on average, LR +DEP predicted their omission scores

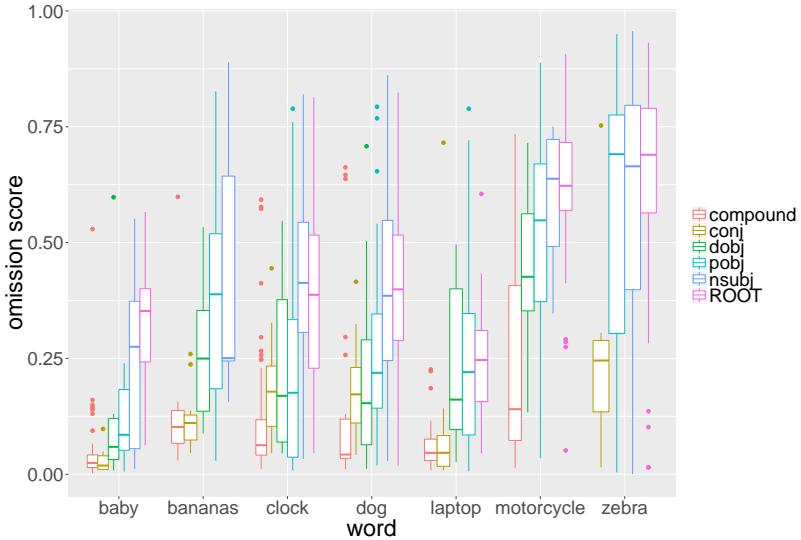

Figure 4.8: Distribution of omission scores per dependency label for the selected word types.

compared to LR WORD.

Figure 4.8 shows the per-dependency omission score distributions for seven top-ranked words. There are clear and large differences in how these words impact the network's representation depending on what grammatical function they fulfil. They all have large omission scores when they occur as NSUBJ (nominal subject) or ROOT, likely due to the fact that these grammatical functions typically have a large contribution to the complete meaning of a sentence. Conversely, all have small omission scores when appearing as CONJ (conjunction): this is probably because in this position they share their contribution with the first, often more important, member of the conjunction, for example in *A cow and its baby eating grass*.

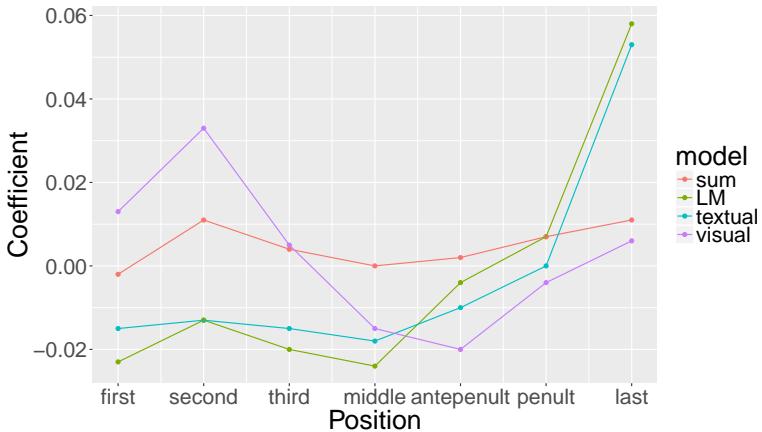

Figure 4.9: Coefficients on the y-axis of LR FULL corresponding to the position variables on the x-axis.

Sensitivity to linear structure

As observed in Section 4.4.3, adding extra information about the position of words explains more of the variance in the case of VISUAL and especially TEXTUAL and LM. Figure 4.9 shows the coefficients corresponding to the position variables in LR FULL. Since the omission scores are measured at the end-of-sentence token, the expectation is that for TEXTUAL and LM, as language models, the words appearing closer to the end of the sentence would have a stronger effect on the omission scores. This seems to be confirmed by the plot as the coefficients for these two networks up until the *antepenult* are all negative.

For the VISUAL model it is less clear what to expect: on the one

hand due to their chain structure, RNNs are better at keeping track of short-distance rather than long-distance dependencies and thus we can expect tokens in positions closer to the end of the sentence to be more important. On the other hand, in English the information structure of a single sentence is expressed via linear ordering: the TOPIC of a sentence appears sentence-initially, and the COMMENT follows. In the context of other text types such as dialog or multi-sentence narrative structure, we would expect COMMENT to often be more important than TOPIC as COMMENT will often contain new information in these cases. In our setting of image captions however, sentences are not part of a larger discourse; it is sentence initial material that typically contains the most important objects depicted in the image, e.g. *two zebras are grazing in tall grass on a savannah*. Thus, for the task of predicting features of the visual scene, it would be advantageous to detect the topic of the sentence and up-weight its importance in the final meaning representation. Figure 4.9 appears to support this hypothesis and the network does learn to pay more attention to words appearing sentence-initially. This effect seems to be to some extent mixed with the recency bias of RNNs as perhaps indicated by the relatively high coefficient of the *last* position for VISUAL.

Lexical versus abstract contexts

We would like to further analyze the kinds of linguistic features that the hidden dimensions of RNNs encode. Previous work Karpathy et al. (2016); Li et al. (2016d) has shown that in response to the task the networks are trained for, individual dimensions in the hidden layers of RNNs can become *specialised* in responding to certain types of triggers, including the tokens or token types at each time step, as

well as the preceding context of each token in the input sentence.

Here we perform a further comparison between the models based on the hypothesis that due to their different objectives, the activations of the dimensions of the last hidden layer of VISUAL are more characterized by semantic relations within contexts, whereas the hidden dimensions in TEXTUAL and LM are more focused on extracting syntactic patterns. In order to quantitatively test this hypothesis, we measure the strength of association between activations of hidden dimensions and either lexical (token n-grams) or structural (dependency label n-grams) types of context.

For each pathway, we define A_i as a discrete random variable corresponding to a binned activation over time steps at hidden dimension i , and C as a discrete random variable indicating the context (where C can be of type ‘word trigram’ or ‘dependency label bigram’, for example). The strength of association between A_i and C can be measured by their mutual information:

$$I(A_i; C) = \sum_{a \in A_i} \sum_{c \in C} p(a, c) \log \left(\frac{p(a, c)}{p(a)p(c)} \right) \quad (4.13)$$

Similarly to (Li et al., 2016d), the activation value distributions are discretized into percentile bins per dimension, such that each bin contains 5% of the marginal density. For context types, we used unigrams, bigrams and trigrams of both dependency labels and words. Figure 4.10 shows the distributions of the mutual information scores for the three networks and the six context types. Note that the scores are not easily comparable between context types, due the different support of the distributions; they are, however, comparable across the networks. The figure shows LM and TEXTUAL as being very similar,

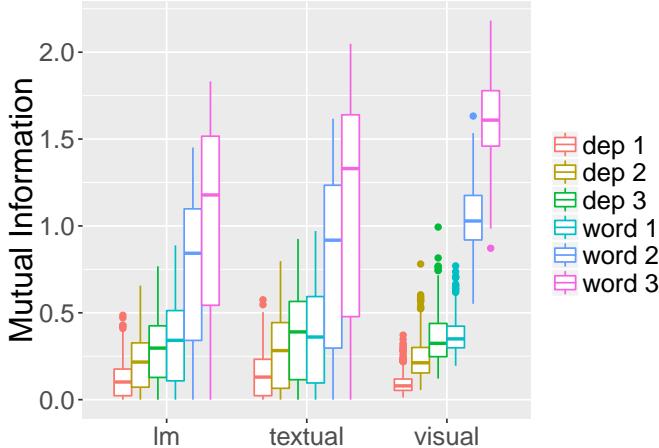

Figure 4.10: Distributions of the mutual information scores for the three networks and the six context types.

while VISUAL exhibits a different distribution. We next compare the models' scores pairwise to pinpoint the nature of the differences.

We use the notation MI_C^{LM} , MI_C^T and MI_C^V to denote the median mutual information score over all dimensions of LM, TEXTUAL and VISUAL respectively, when considering context C . We then compute log ratios $\log(\text{MI}_C^T / \text{MI}_C^V)$ and $\log(\text{MI}_C^{LM} / \text{MI}_C^T)$ for all six context types C . In order to quantify variability we bootstrap this statistic with 5000 replicates. Figure 4.11 shows the resulting bootstrap distributions for uni-, bi-, and trigram contexts, in the word and dependency conditions.

The clear pattern is that for TEXTUAL versus VISUAL, the log ratios are much higher in the case of the dependency contexts, with no overlap between the bootstrap distributions. Thus, in general, the size of the relative difference between TEXTUAL and VISUAL median mutual information score is much more pronounced for dependency

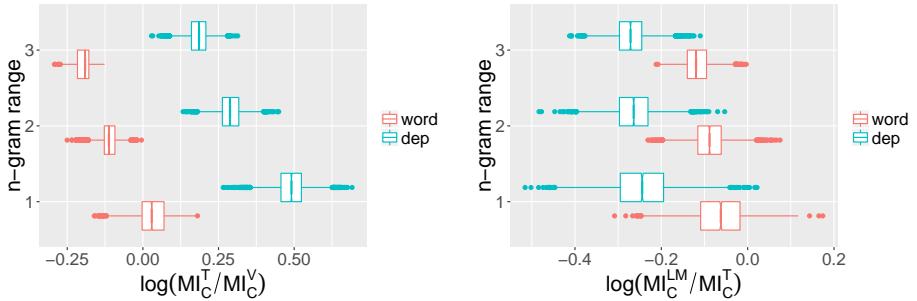

Figure 4.11: Bootstrap distributions of log ratios of median mutual information scores for word and dependency contexts. Left: TEXTUAL vs VISUAL; right: LM vs TEXTUAL

context types. This suggests that features that are encoded by the hidden dimensions of the models are indeed different, and that the features encoded by TEXTUAL are more associated with syntactic constructions than in the case of VISUAL. In contrast, when comparing LM with TEXTUAL, the difference between context types is much less pronounced, with distributions overlapping. Though the difference is small, it goes in the direction of the dimensions of the TEXTUAL model showing higher sensitivity towards dependency contexts.

The mutual information scores can be used to pinpoint specific dimensions of the hidden activation vectors which are strongly associated with a particular type of context. Table 4.2 lists for each network the dimension with the highest mutual information score with respect to the *dependency trigram* context type, together with the top five contexts where these dimensions carry the highest value. In spite of the quantitative difference between the networks discussed above, the dimensions which come up top seem to be capturing something quite similar for the three networks: (a part of) a construction

Table 4.2: Dimensions most strongly associated with the dependency trigram context type, and the top five contexts in which these dimensions have high values.

Network	Dimension	Examples
LM	511	cookie/pobj attached/acl to/prep people/pobj sitting/acl in/prep purses/pobj sitting/pcomp on/prep and/cc talks/conj on/prep desserts/pobj sitting/acl next/advmod
TEXTUAL	735	male/root on/prep a/det person/nsubj rides/root a/det man/root carrying/acl a/det man/root on/prep a/det person/root on/prep a/det
VISUAL	875	man/root riding/acl a/det man/root wearing/acl a/det is/aux wearing/conj a/det a/det post/pobj next/advmod one/nummod person/nsubj is/aux

with an animate root or subject modified by a participle or a prepositional phrase, though this is somewhat less clean-cut for the VISUAL pathway where only two out of five top context clearly conform to this pattern. Other interesting templates can be found by visual inspection of the contexts where high-scoring dimensions are active; for example, dimension 324 of LM is high for *word bigram* contexts including *people preparing, gets ready, man preparing, woman preparing, teenager preparing*.

Discussion

The goal of our paper is to propose novel methods for the analysis of the encoding of linguistic knowledge in RNNs trained on language tasks. We focused on developing quantitative methods to measure the importance of different kinds of words for the performance of such models. Furthermore, we proposed techniques to explore what kinds of linguistic features the models learn to exploit beyond lexical cues.

Using the IMAGINET model as our case study, our analyses of the hidden activation patterns show that the VISUAL model learns an abstract representation of the information structure of a single sentence in the language, and pays selective attention to lexical categories and grammatical functions that carry semantic information. In contrast, the language model TEXTUAL is sensitive to features of a more syntactic nature. We have also shown that each network contains specialized units which are tuned to both lexical and structural patterns that are useful for the task at hand.

Generalizing to other architectures

For other RNN architectures such as LSTMs and their bi-directional variants, measuring the contribution of tokens to their predictions (or the omission scores) can be straight-forwardly computed using their hidden state at the last time step used for prediction. Furthermore, the technique can be applied in general to other architectures which map variable-length linguistic expressions to the same fixed dimensional space and perform predictions based on these embeddings. This includes tree-structured Recursive Neural Network models such

as the Tree-LSTM introduced in (Tai et al., 2015a), or the CNN architecture of (Kim, 2014) for sentence classification. However, the presented analysis and results regarding word positions can only be meaningful for Recurrent Neural Networks as they compute their representations sequentially and are not limited by fixed window sizes.

A limitation of the generalizability of our analysis is that in the case of bi-directional architectures, the interpretation of the features extracted by the RNNs that process the input tokens in the reversed order might be hard from a linguistic point of view.

Future directions

In future we would like to apply the techniques introduced in this paper to analyze the encoding of linguistic form and function of recurrent neural models trained on different objectives, such as neural machine translation systems Sutskever et al. (2014) or the purely distributional sentence embedding system of (Kiros et al., 2015). A number of recurrent neural models rely on a so-called attention mechanism, first introduced by (Bahdanau et al., 2015a) under the name of soft alignment. In these networks attention is explicitly represented, and it would be interesting to see how our method of discovering implicit attention, the omission score, compares. For future work we also propose to collect data where humans assess the importance of each word in a sentence and explore the relationship between omission scores for various models and human annotations. Finally, one of the benefits of understanding how linguistic form and function is represented in RNNs is that it can provide insight into how to improve systems. We plan to draw on lessons learned from our analyses in order to develop models with better general-purpose sentence rep-

resentations.

5

Imagination Improves Multimodal Translation

abstract We decompose multimodal translation into two sub-tasks: learning to translate and learning visually grounded representations. In a multitask learning framework, translations are learned in an attention-based encoder-decoder, and grounded representations are learned through image representation prediction. Our approach improves translation performance compared to the state of the art on the Multi30K dataset. Furthermore, it is equally effective if we train the image prediction task on the external MS COCO dataset, and we find improvements if we train the translation model on the external News Commentary parallel text.

Introduction

Multimodal machine translation is the task of translating sentences in context, such as images paired with a parallel text Specia et al. (2016a). This is an emerging task in the area of multilingual multimodal natural language processing. Progress on this task may prove useful for translating the captions of the images illustrating online news articles, and for multilingual closed captioning in international television and cinema.

Initial efforts have not convincingly demonstrated that visual context can improve translation quality. In the results of the First Multimodal Translation Shared Task, only three systems outperformed an off-the-shelf text-only phrase-based machine translation model, and the best performing system was equally effective with or without the visual features Specia et al. (2016a). There remains an open question about how translation models should take advantage of visual context.

We present a multitask learning model that decomposes multimodal translation into learning a translation model and learning visually grounded representations. This decomposition means that our model can be trained over external datasets of parallel text or described images, making it possible to take advantage of existing resources. Figure 5.1 presents an overview of our model, Imagination, in which source language representations are shared between tasks through the Shared Encoder. The translation decoder is an attention-based neural machine translation model Bahdanau et al. (2015b), and the image prediction decoder is trained to predict a global feature vector of an image that is associated with a sentence (Chrupała et al.,

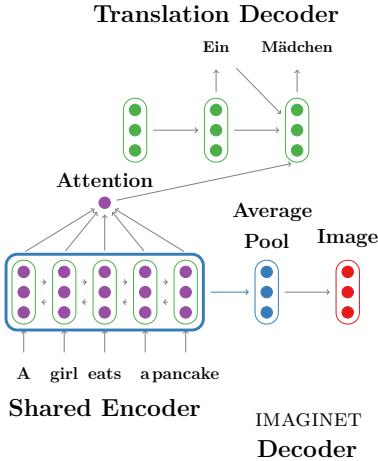

Figure 5.1: The Imagination model learns visually-grounded representations by sharing the encoder network between the Translation Decoder with image prediction in the IMAGINET Decoder.

2015b, IMAGINET). This decomposition encourages grounded learning in the shared encoder because the IMAGINET decoder is trained to imagine the image associated with a sentence. It has been shown that grounded representations are qualitatively different from their text-only counterparts Kdr et al. (2016) and correlate better with human similarity judgements Chrupaa et al. (2015b). We assess the success of the grounded learning by evaluating the image prediction model on an image–sentence ranking task to determine if the shared representations are useful for image retrieval Hodosh et al. (2013b). In contrast with most previous work, our model does not take images as input at translation time, rather it learns grounded representations in the shared encoder.

We evaluate Imagination on the Multi30K dataset Elliott et al. (2016a) using a combination of in-domain and out-of-domain data. In the in-domain experiments, we find that multitasking translation

with image prediction is competitive with the state of the art. Our model achieves 55.8 Meteor as a single model trained on multimodal in-domain data, and 57.6 Meteor as an ensemble.

In the experiments with out-of-domain resources, we find that the improvement in translation quality holds when training the IMAGINET decoder on the MS COCO dataset of described images Chen et al. (2015). Furthermore, if we significantly improve our text-only baseline using out-of-domain parallel text from the News Commentary corpus Tiedemann (2012), we still find improvements in translation quality from the auxiliary image prediction task. Finally, we report a state-of-the-art result of 59.3 Meteor on the Multi30K corpus when ensembling models trained on in- and out-of-domain resources.

The main contributions of this paper are:

- We show how to apply multitask learning to multimodal translation. This makes it possible to train models for this task using external resources alongside the expensive triple-aligned source-target-image data.
- We decompose multimodal translation into two tasks: learning to translate and learning grounded representations. We show that each task can be trained on large-scale external resources, e.g. parallel news text or images described in a single language.
- We present a model that achieves state of the art results without using images as an input. Instead, our model learns visually grounded source language representations using an auxiliary image prediction objective. Our model does not need any additional parameters to translate unseen sentences.

Problem Formulation

Multimodal translation is the task of producing target language translation y , given the source language sentence x and additional context, such as an image v Specia et al. (2016a). Let x be a source language sentence consisting of N tokens: x_1, x_2, \dots, x_n and let y be a target language sentence consisting of M tokens: y_1, y_2, \dots, y_m . The training data consists of tuples $\mathcal{D} \in (x, y, v)$, where x is a description of image v , and y is a translation of x .

Multimodal translation has previously been framed as minimising the negative log-likelihood of a translation model that is additionally conditioned on the image, i.e. $J(\theta) = -\sum_j \log p(y_j|y_{<j}, x, v)$. Here, we decompose the problem into learning to translate and learning visually grounded representations. The decomposition is based on sharing parameters θ between these two tasks, and learning task-specific parameters ϕ . We learn the parameters in a multitask model with shared parameters in the source language encoder. The translation model has task-specific parameters ϕ^t in the attention-based decoder, which are optimized through the translation loss $J_T(\theta, \phi^t)$. Grounded representations are learned through an image prediction model with task-specific parameters ϕ^g in the image-prediction decoder by minimizing $J_G(\theta, \phi^g)$. The joint objective is given by mixing the translation and image prediction tasks with the parameter w :

$$J(\theta, \phi) = w J_T(\theta, \phi^t) + (1 - w) J_G(\theta, \phi^g) \quad (5.1)$$

Our decomposition of the problem makes it straightforward to optimise this objective without paired tuples, e.g. where we have an external dataset of described images $\mathcal{D}_{image} \in (x, v)$ or an external

parallel corpus $\mathcal{D}_{text} \in (x, y)$.

We train our multitask model following the approach of (Luong et al., 2016). We define a primary task and an auxiliary task, and a set of parameters θ to be shared between the tasks. A minibatch of updates is performed for the primary task with probability w , and for the auxiliary task with $1 - w$. The primary task is trained until convergence and weight w determines the frequency of parameter updates for the auxiliary task.

Imagination Model

Shared Encoder

The encoder network of our model learns a representation of a sequence of N tokens $x_{1\dots n}$ in the source language with a bidirectional recurrent neural network Schuster & Paliwal (1997). This representation is shared between the different tasks. Each token is represented by a one-hot vector \mathbf{x}_i , which is mapped into an embedding \mathbf{e}_i through a learned matrix \mathbf{E} :

$$\mathbf{e}_i = \mathbf{x}_i \cdot \mathbf{E} \quad (5.2)$$

A sentence is processed by a pair of recurrent neural networks, where one captures the sequence left-to-right (forward), and the other captures the sequence right-to-left (backward). The initial state of the encoder \mathbf{h}_{-1} is a learned parameter:

$$\overrightarrow{\mathbf{h}_i} = \overrightarrow{\text{RNN}}(\overrightarrow{\mathbf{h}_{i-1}}, \mathbf{e}_i) \quad (5.3)$$

$$\overleftarrow{\mathbf{h}_i} = \overleftarrow{\text{RNN}}(\overleftarrow{\mathbf{h}_{i-1}}, \mathbf{e}_i) \quad (5.4)$$

Each token in the source language input sequence is represented by a concatenation of the forward and backward hidden state vectors:

$$\mathbf{h}_i = [\vec{\mathbf{h}}_i; \overleftarrow{\mathbf{h}}_i] \quad (5.5)$$

Neural Machine Translation Decoder

The translation model decoder is an attention-based recurrent neural network Bahdanau et al. (2015b). Tokens in the decoder are represented by a one-hot vector \mathbf{y}_j , which is mapped into an embedding \mathbf{e}_j through a learned matrix \mathbf{E}_y :

$$\mathbf{e}_j = \mathbf{y}_j \cdot \mathbf{E}_y \quad (5.6)$$

The inputs to the decoder are the previously predicted token \mathbf{y}_{j-1} , the previous decoder state \mathbf{d}_{j-1} , and a timestep-dependent context vector \mathbf{c}_j calculated over the encoder hidden states:

$$\mathbf{d}_j = \text{RNN}(\mathbf{d}_{j-1}, \mathbf{y}_{j-1}, \mathbf{e}_j) \quad (5.7)$$

The initial state of the decoder \mathbf{d}_1 is a nonlinear transform of the mean of the encoder states, where \mathbf{W}_{init} is a learned parameter:

$$\mathbf{d}_1 = \tanh(\mathbf{W}_{init} \cdot \frac{1}{N} \sum_i^N \mathbf{h}_i) \quad (5.8)$$

The context vector c_j is a weighted sum over the encoder hidden states, where N denotes the length of the source sentence:

$$\mathbf{c}_j = \sum_{i=1}^N \alpha_{ji} \mathbf{h}_i \quad (5.9)$$

The α_{ji} values are the proportion of which the encoder hidden state vectors $\mathbf{h}_{1\dots n}$ contribute to the decoder hidden state when producing the j th token in the translation. They are computed by a feed-forward neural network, where \mathbf{v}_a , \mathbf{W}_a and \mathbf{U}_a are learned parameters:

$$\alpha_{ji} = \frac{\exp(e_{ji})}{\sum_{l=1}^N \exp(e_{li})} \quad (5.10)$$

$$e_{ji} = \mathbf{v}_a \cdot \tanh(\mathbf{W}_a \cdot \mathbf{d}_{j-1} + \mathbf{U}_a \cdot \mathbf{h}_i) \quad (5.11)$$

From the hidden state \mathbf{d}_j the network predicts the conditional distribution of the next token y_j , given a target language embedding \mathbf{e}_{j-1} of the previous token, the current hidden state \mathbf{d}_j , and the calculated context vector \mathbf{c}_j . Note that at training time, y_{j-1} is the true observed token; whereas for unseen data we use the inferred token \hat{y}_{j-1} sampled from the output of the softmax:

$$p(y_j | y_{<j}, c) = \text{softmax}(\tanh(\mathbf{e}_{j-1} + \mathbf{d}_j + \mathbf{c}_j)) \quad (5.12)$$

The translation model is trained to minimise the negative log likelihood of predicting the target language output:

$$J_{NLL}(\theta, \phi^t) = - \sum_j \log p(y_j | y_{<j}, x) \quad (5.13)$$

Imaginet Decoder

The image prediction decoder is trained to predict the visual feature vector of the image associated with a sentence Chrupała et al. (2015b). It encourages the shared encoder to learn grounded representations for the source language.

A source language sentence is encoded using the Shared Encoder, as described in Section 5.3.1. Then we transform the shared encoder representation into a single vector by taking the mean pool over the hidden state annotations, the same way we initialise the hidden state of the translation decoder (Eqn. 5.8). This sentence representation is the input to a feed-forward neural network that predicts the visual feature vector $\hat{\mathbf{v}}$ associated with a sentence with parameters \mathbf{W}_{vis} :

$$\hat{\mathbf{v}} = \tanh(\mathbf{W}_{\text{vis}} \cdot \frac{1}{N} \sum_i^N \mathbf{h}_i) \quad (5.14)$$

This decoder is trained to predict the true image vector \mathbf{v} with a margin-based objective, parameterised by the minimum margin α , and the cosine distance $d(\cdot, \cdot)$. A margin-based objective has previously been used in grounded representation learning Vendrov et al. (2016); ?. The contrastive examples \mathbf{v}' are drawn from the other instances in a minibatch:

$$J_{MAR}(\theta, \phi^t) = \sum_{\mathbf{v}' \neq \mathbf{v}} \max\{0, \alpha - d(\hat{\mathbf{v}}, \mathbf{v}) + d(\hat{\mathbf{v}}, \mathbf{v}')\} \quad (5.15)$$

Table 5.1: The datasets used in our experiments.

Data

We evaluate our model using the benchmark Multi30K dataset Elliott et al. (2016a), which is the largest collection of images paired with sentences in multiple languages. This dataset contains 31,014 images paired with an English language sentence and a German language translation: 29,000 instances are reserved for training, 1,014 for development, and 1,000 for evaluation.*

The English and German sentences are preprocessed by normalising the punctuation, lowercasing and tokenizing the text using the Moses toolkit. We additionally decompound the German text using Zmorge Sennrich & Kunz (2014). This results in vocabulary sizes of

*The Multi30K dataset also contains 155K independently collected descriptions in German and English. In order to make our experiments more comparable with previous work, we do not make use of this data.

10,214 types for English and 16,022 for German.

We also use two external datasets to evaluate our model: the MS COCO dataset of English described images Chen et al. (2015), and the English-German News Commentary parallel corpus Tiedemann (2012). When we perform experiments with the News Commentary corpus, we first calculate a 17,597 sub-word vocabulary using SentencePiece Schuster & Nakajima (2012) over the concatenation of the Multi30K and News Commentary datasets. This gives us a shared vocabulary for the external data that reduces the number of out-of-vocabulary tokens.

Images are represented by 2048D vectors extracted from the ‘pool5/7x7_s1’ layer of the GoogLeNet v3 CNN Szegedy et al. (2015).

Experiments

We evaluate our multitasking approach with in- and out-of-domain resources. We start by reporting results of models trained using only the Multi30K dataset. We also report the results of training the IMAGINE decoder with the COCO dataset. Finally, we report results on incorporating the external News Commentary parallel text into our model. Throughout, we report performance of the En→De translation using Meteor Denkowski & Lavie (2014) and BLEU Papineni et al. (2002) against lowercased tokenized references.

Hyperparameters

The encoder is a 1000D Gated Recurrent Unit bidirectional recurrent neural network (Cho et al., 2014c, GRU) with 620D embeddings. We share all of the encoder parameters between the primary and auxil-

iary task. The translation decoder is a 1000D GRU recurrent neural network, with a 2000D context vector over the encoder states, and 620D word embeddings Sennrich et al. (2017). The Imagenet decoder is a single-layer feed-forward network, where we learn the parameters $\mathbf{W}_{\text{vis}} \in \mathbb{R}^{2048 \times 2000}$ to predict the true image vector with $\alpha = 0.1$ for the Imagenet objective (Equation 5.15). The models are trained using the Adam optimiser with the default hyperparameters Kingma & Ba (2015) in minibatches of 80 instances. The translation task is defined as the primary task and convergence is reached when BLEU has not increased for five epochs on the validation data. Gradients are clipped when their norm exceeds 1.0. Dropout is set to 0.2 for the embeddings and the recurrent connections in both tasks Gal & Ghahramani (2016). Translations are decoded using beam search with 12 hypotheses.

In-domain experiments

We start by presenting the results of our multitask model trained using only the Multi30K dataset. We compare against state-of-the-art approaches and text-only baselines. Moses is the phrase-based machine translation model Koehn et al. (2007) reported in Specia et al. (2016a). NMT is a text-only neural machine translation model. (Calixto et al., 2017a) is a double-attention model over the source language and the image. (Calixto & Liu, 2017) is a multimodal translation model that conditions the decoder on semantic image vector extracted from the VGG-19 CNN. (Hitschler et al., 2016) uses visual features in a target-side retrieval model for translation. (Toyama et al., 2016) is most comparable to our approach: it is a multimodal variational NMT model that infers latent variables to represent the

source language semantics from the image and linguistic data.

Table 5.2 shows the results of this experiment. We can see that the combination of the attention-based translation model and the image prediction model is a 1.8 Meteor point improvement over the NMT baseline, but it is 1.1 Meteor points worse than the strong Moses baseline. Our approach is competitive with previous approaches that use visual features as inputs to the decoder and the target-side reranking model. It also competitive with (Toyama et al., 2016), which also only uses images for training. These results confirm that our multitasking approach uses the image prediction task to improve the encoder of the translation model.

External described image data

Recall from Section 5.2 that we are interested in scenarios where x , y , and v are drawn from different sources. We now experiment

with separating the translation data from the described image data using \mathcal{D}_{image} : MS COCO dataset of 83K described images[†] and \mathcal{D}_{text} : Multi30K parallel text.

Table 5.3 shows the results of this experiment. We find that there is no significant difference between training the IMAGINET decoder on in-domain (Multi30K) or out-of-domain data (COCO). This result confirms that we can separate the parallel text from the described

[†]Due to differences in the vocabularies of the respective datasets, we do not train on examples where more than 10% of the tokens are out-of-vocabulary in the Multi30K dataset.

images.

External parallel text data

We now experiment with training our model on a combination of the Multi30K and the News Commentary English-German data. In these experiments, we concatenate the Multi30K and News Commentary datasets into a single \mathcal{D}_{text} training dataset, similar to (Freitag & Al-Onaizan, 2016). We compare our model against (Calixto et al., 2017a), who pre-train their model on the WMT’15 English-German parallel text and back-translate Sennrich et al. (2016) additional sentences from the bilingual independent descriptions in the Multi30K dataset (Footnote 2).

Table 5.4 presents the results. The text-only NMT model using sub-words is 1.2 Meteor points lower than decompounding the German text. Nevertheless, the model trained over a concatenation of the parallel texts is a 2.7 Meteor point improvement over this baseline

(+ NC) and matches the performance of our Multitasking model that uses only in-domain data (Section 5.5.2). We do not see an additive improvement for the multitasking model with the concatenated parallel text and the in-domain data (+ Imagination) using a training objective interpolation of $w = 0.89$ (the ratio of the training dataset sizes). This may be because we are essentially learning a translation model and the updates from the IMAGINET decoder are forgotten. Therefore, we experiment with multitasking the concatenated parallel text and the COCO dataset ($w = 0.5$). We find that balancing the datasets improves over the concatenated text model by 0.4 Meteor (+ Imagination (COCO)). Our multitasking approach improves upon Calixto et al. by 0.3 Meteor points. Our model can be trained in 48 hours using 240K parallel sentences and 414K described images from out-of-domain datasets. Furthermore, recall that our model does not use images as an input for translating unseen data, which results in 6.2% fewer parameters compared to using the 2048D Inception-V3 visual features to initialise the hidden state of the decoder.

Ensemble results

Table 5.5 presents the results of ensembling different randomly initialised models. We achieve a start-of-the-art result of 57.6 Meteor for a model trained on only in-domain data. The improvements are more pronounced for the models trained using sub-words and out-of-domain data. An ensemble of baselines trained on sub-words is initially worse than an ensemble trained on Zmorge decompounded words. However, we always see an improvement from ensembling models trained on in- and out-of-domain data. Our best ensemble is trained on Multi30K parallel text, the News Commentary parallel

text, and the COCO descriptions to set a new state-of-the-art result of 59.3 Meteor.

Multi30K 2017 results

We also evaluate our approach against 16 submissions to the WMT Shared Task on Multimodal Translation and Multilingual Image Description Elliott et al. (2017a). This shared task features a new evaluation dataset: Multi30K Test 2017 Elliott et al. (2017a), which contains 1,000 new evaluation images. The shared task submissions are evaluated with Meteor and human direct assessment Graham et al. (2017). We submitted two systems, based on whether they used only the Multi30K dataset (constrained) or used additional external resources (unconstrained). Our constrained submission is an ensemble of three Imagination models trained over only the Multi30K training

data. This achieves a Meteor score of 51.2, and a joint 3rd place ranking according to human assessment. Our unconstrained submission is an ensemble of three Imagination models trained with the Multi30K, News Commentary, and MS COCO datasets. It achieves a Meteor score of 53.5, and 2nd place in the human assessment.

Qualitative examples

Table 5.6 shows examples of where the multitasking model improves or worsens translation performance compared to the baseline model[‡]. The first example shows that the baseline model makes a significant error in translating the pose of the children, translating “on their stomachs” as “on their faces”). The middle example demonstrates that the baseline model translates the dog as walking (“läuft”) and then makes grammatical and sense errors after the clause marker. Both models neglect to translate the word “dangling”, which is a low-frequency word in the training data. There are instances where the baseline produces better translations than the multitask model: In the bottom example, our model translates a bird flying through the water (“durch”) instead of “over” the water.

Discussion

Does the model learn grounded representations?

A natural question to ask is whether the multitask model is actually learning representations that are relevant for the images. We answer this question by evaluating the Imagenet decoder in an image—

[‡]We used MT-ComparEval Klejch et al. (2015)

(a) Nearest neighbours for “a native woman is working on a craft project.”

(b) Nearest neighbours for “there is a cafe on the street corner with an oval painting on the side of the building.”

Figure 5.2: We can interpret the IMAGINET Decoder by visualising the predictions made by our model.

sentence ranking task. Here the input is a source language sentence, from which we predict its image vector $\hat{\mathbf{v}}$. The predicted vector $\hat{\mathbf{v}}$ can be compared against the true image vectors \mathbf{v} in the evaluation data using the cosine distance to produce a ranked order of the images. Our model returns a median rank of 11.0 for the true image compared to the predicted image vector. Figure 5.2 shows examples of the nearest neighbours of the images predicted by our multitask model. We can see that the combination of the multitask source language representations and IMAGINET decoder leads to the prediction of relevant images. This confirms that the shared encoder is indeed learning visually grounded representations.

The effect of visual feature vectors

We now study the effect of varying the Convolutional Neural Network used to extract the visual features used in the Imagenet decoder. It has previously been shown that the choice of visual features can affect

	Meteor	Median Rank
Inception-V3	56.0 ± 0.1	11.0 ± 0.0
Resnet-50	54.7 ± 0.4	11.7 ± 0.5
VGG-19	53.6 ± 1.8	13.0 ± 0.0

Table 5.7: The type of visual features predicted by the IMAGINET Decoder has a strong impact on the Multitask model performance.

the performance of vision and language models Jabri et al. (2016a); Kiela et al. (2016). We compare the effect of training the IMAGINET decoder to predict different types of image features, namely: 4096D features extracted from the ‘fc7’ layer of the VGG-19 model Simonyan & Zisserman (2015), 2048D features extracted from the ‘pool5/7x7_s1’ layer of InceptionNet V3 Szegedy et al. (2015), and 2048D features extracted from ‘avg_pool’ layer of ResNet-50 He et al. (2016a). Table 5.7 shows the results of this experiment. There is a clear difference between predicting the 2048D vectors (Inception-V3 and ResNet-50) compared to the 4096D vector from VGG-19). This difference is reflected in both the translation Meteor score and the Median rank of the images in the validation dataset. This is likely because it is easier to learn the parameters of the image prediction model that has fewer parameters (8.192 million for VGG-19 vs. 4.096 million for Inception-V3 and ResNet-50). However, it is not clear why there is such a pronounced difference between the Inception-V3 and ResNet-50 models[§].

[§]We used pre-trained CNNs (<https://github.com/fchollet/deep-learning-models>), which claim equal ILSVRC object recognition performance for both models: 7.8% top-5 error with a single-model and single-crop.

Related work

Initial work on multimodal translation used semantic or spatially-preserving image features as inputs to a translation model. Semantic image features are typically extracted from the final layer of a pre-trained object recognition CNN, e.g. ‘pool5/7x7_s1’ in GoogLeNet Szegedy et al. (2015). This type of vector has been used as input to the encoder Elliott et al. (2015); Huang et al. (2016), the decoder Libovický et al. (2016), or as features in a phrase-based translation model Shah et al. (2016); Hitschler et al. (2016). Spatially-preserving image features are extracted from deeper inside a CNN, where the position of a feature is related to its position in the image. These features have been used in “double-attention models”, which calculate independent context vectors for the source language and a convolutional image features Calixto et al. (2016); Caglayan et al. (2016); Calixto et al. (2017a). We use an attention-based translation model but our multitask model does not use images for translation.

More related to our work is an extension of Variational Neural Machine Translation to infer latent variables to *explicitly* model the semantics of source sentences from visual and linguistic information Toyama et al. (2016). They report improvements on the Multi30K data set but their model needs additional parameters in the “neural inferrer” modules. In our model, the grounded semantics are represented *implicitly* in the shared encoder. They assume Source-Target-Image training data, whereas our approach achieves equally good results if we train on separate Source-Image and Source-Target datasets. (Saha et al., 2016b) study cross-lingual image description where the task is to generate a sentence in language L_1 given the image, using only Image- L_2 and L_1 - L_2 training corpora. They pro-

pose a Correlational Encoder-Decoder to model the Image- L_2 and L_1 - L_2 data, which learns correlated representations for paired Image- L_2 data and decodes L_1 from the joint representation. Similar to our work, the encoder is trained by minimizing two loss functions: the Image- L_2 correlation loss, and the L_1 decoding cross-entropy loss. (Nakayama & Nishida, 2017b) consider a zero-resource problem, where the task is to translate from L_1 to L_2 with only Image- L_1 and Image- L_2 corpora. Their model embeds the image, L_1 , and L_2 in a joint multimodal space learned by minimizing a multi-task ranking loss between both pairs of examples. In this paper, we focus on *enriching* source language representations with visual information instead of zero-resource learning.

Multitask Learning improves the generalisability of a model by requiring it to be useful for more than one task Caruana (1997). This approach has recently been used to improve the performance of sentence compression using eye gaze as an auxiliary task Klerke et al. (2016), and to improve shallow parsing accuracy through the auxiliary task of predicting keystrokes in an out-of-domain corpus Plank (2016). More recently, (Bingel & Søgaard, 2017) analysed the beneficial relationships between primary and auxiliary sequential prediction tasks. In the translation literature, multitask learning has been used to learn a one-to-many languages translation model Dong et al. (2015), a multi-lingual translation model with a single attention mechanism shared across multiple languages Firat et al. (2016), and in multitask sequence-to-sequence learning without an attention-based decoder Luong et al. (2016). We explore the benefits of grounded learning in the specific case of multimodal translation. We combine sequence prediction with continuous (image) vector prediction, com-

pared to previous work which multitasks different sequence prediction tasks.

Visual representation prediction has been studied using static images or videos. (Lin & Parikh, 2015) use a conditional random field to imagine the composition of a clip-art scene for visual paraphrasing and fill-in-the-blank tasks. (Chrupała et al., 2015b) predict the image vector associated with a sentence using an L2 loss; they found this improves multi-modal word similarity compared to text-only baselines. (Gelderloos & Chrupała, 2016) predict the image vector associated with a sequence of phonemes using a max-margin loss, similar to our image prediction objective. (Collell et al., 2017) learn to predict the visual feature vector associated with a word for word similarity and relatedness tasks. As a video reconstruction problem, (Srivastava et al., 2015) propose an LSTM Autoencoder to predict video frames as a reconstruction task or as a future prediction task. (Pasunuru & Bansal, 2017) propose a multitask model for video description that combines unsupervised video reconstruction, lexical entailment, and video description. They find improvements from using out-of-domain resources for entailment and video prediction, similar to the improvements we find from using out-of-domain parallel text and described images.

Conclusion

We decompose multimodal translation into two sub-problems: learning to translate and learning visually grounded representations. In a multitask learning framework, we show how these sub-problems can be addressed by sharing an encoder between a translation model and

an image prediction model[¶]. Our approach achieves state-of-the-art results on the Multi30K dataset without using images for translation. We show that training on separate parallel text and described image datasets does not hurt performance, encouraging future research on multitasking with diverse sources of data. Furthermore, we still find improvements from image prediction when we improve our text-only baseline with the out-of-domain parallel text. Future work includes adapting our decomposition to other NLP tasks that may benefit from out-of-domain resources, such as semantic role labelling, dependency parsing, and question-answering; exploring methods for inputting the (predicted) image into the translation model; experimenting with different image prediction architectures; multitasking different translation languages into a single shared encoder; and multitasking in both the encoder and decoder(s).

Acknowledgments

We are grateful to the anonymous reviewers for their feedback. We thank Joost Bastings for sharing his multitasking Nematus model, Wilker Aziz for discussions about formulating the problem, Stella Frank for finding and explaining the qualitative examples to us, and Afra Alishahi, Grzegorz Chrupała, and Philip Schulz for feedback on earlier drafts of the paper. DE acknowledges the support of an Amazon Research Award, NWO Vici grant nr. 277-89-002 awarded to K. Sima'an, and a hardware grant from the NVIDIA Corporation.

Lessons learned in multilingual grounded language learning

abstract Recent work has shown how to learn better visual-semantic embeddings by leveraging image descriptions in more than one language. Here, we investigate in detail which conditions affect the performance of this type of grounded language learning model. We show that multilingual training improves over bilingual training, and that low-resource languages benefit from training with higher-resource languages. We demonstrate that a multilingual model can be trained equally well on either translations or comparable sentence pairs, and that annotating the same set of images in multiple language enables further improvements via an additional caption-caption ranking objective.

Introduction

Multimodal representation learning is largely motivated by evidence of perceptual grounding in human concept acquisition and representation Barsalou et al. (2003). It has been shown that visually grounded word and sentence-representations Kiela et al. (2014); Baroni (2016); Elliott & Kdr (2017); Kiela et al. (2017); Yoo et al. (2017) improve performance on the downstream tasks of paraphrase identification, semantic entailment, and multimodal machine translation Dolan et al. (2004); Marelli et al. (2014b); Specia et al. (2016b). Multilingual sentence representations have also been successfully applied to many-languages-to-one character-level machine translation Chung et al. (2016b) and multilingual dependency parsing Ammar et al. (2016).

Recently, Gella et al. (2017) proposed to learn both bilingual and multimodal sentence representations using images paired with captions independently collected in English and German. Their results show that bilingual training improves image-sentence ranking performance over a monolingual baseline, and it improves performance on semantic textual similarity benchmarks (Agirre et al., 2014, 2015). These findings suggest that it may be beneficial to consider another language as another *modality* in a monolingual grounded language learning model. In the grounded learning scenario, descriptions of an image in multiple languages can be considered as multiple views of the same or closely related data. These additional views can help overcome the problems of data sparsity, and have practical implications for efficiently collecting image-text datasets in different languages.

(a) A translation tuple

(b) A comparable pair

Figure 6.1: An example taken from the *Translation* and *Comparable* portions of the Multi30K dataset. The translation portion (a) contains professional translations of the English captions into German, French, and Czech. The comparable portion (b) consists of five independently crowdsourced English and German descriptions, given only the image. Note that the sentences in (b) convey different information from the English–German translation pair in (a).

In real-life applications, many tasks and domains can involve code switching Barman et al. (2014), which is easier to deal with using a multilingual model. Furthermore, it is more convenient to maintain a single multilingual system than one system for each considered language. However, there is a need for a systematic exploration of the conditions under which it is useful to add additional views of the data. We investigate the impact of the following conditions on the performance of a multilingual grounded language learning model in sentence and image retrieval tasks:

Additional languages. Multilingual models have not been explored yet in a multimodal setting. We investigate the contribution of adding more than one language by performing bilingual experiments on English and German (Section 6.5) as well as adding French and Czech captioned images (Section 6.6).

Data alignment: We assess the performance of a multilingual models trained using either captions that are translations of each other, or captions that are independently collected in different languages for the same set of images. The two scenarios are illustrated in Figure 6.1. Additionally we consider the setup when non-overlapping sets of images and their captions are collected in different languages. Such disjoint settings have been explored in pivot-based multimodal representation learning Funaki & Nakayama (2015); Rajendran et al. (2015) or zero-shot multi-modal machine translation Nakayama & Nishida (2017a). We compare translated vs. independently collected captions in Sections 6.5.2 and 6.6.1, and overlapping vs. disjoint images in Section 6.5.3.

High-to-low resource transfer: In Section 6.6.2 we investigate whether low-resource languages benefit from jointly training on larger data sets from higher-resource languages. This type of transfer has previously been shown to be effective in machine translation (e.g., Zoph et al., 2016).

Training objective: In addition to learning to map images to sentences, we study the effect of also learning relationships between captions of the same image in different languages Gella et al. (2017). We assess the contribution of such a caption–caption ranking objective throughout our experiments.

Our results show that multilingual joint training improves upon bilingual joint training, and that grounded sentence representations for a low-resource language can be substantially improved with data from different high-resource languages. Our results suggest that independently-collected captions are more useful than translated captions, for the task of learning multilingual multimodal sentence embeddings. Finally, we recommend to collect captions for the same set of images in multiple languages, due to the benefits of the additional caption–caption ranking objective function.

Related work

Learning visually grounded word-representations has been an active area of research in the fields of multi-modal semantics and cross-situational word-learning. Such perceptually-grounded word repre-

¹Gloss: Three men and two women with a South-East Asian appearance eat out of bowls at a black table, on which there are, among other things, paper cups and a bag; in the background there are other people and tables.

sentations have been shown to lead to higher correlation with human judgements on word-similarity benchmarks such as WordSim353 Finkelstein et al. (2001b) or SimLex999 Hill et al. (2015) compared to uni-modal representations Kdr et al. (2015); Bruni et al. (2014); Kiela & Bottou (2014).

Grounded representations of sentences that are learned from image-caption data sets also improve performance on a number of sentence-level tasks Kiela et al. (2017); Yoo et al. (2017) when used as additional features to skip-thought vectors Kiros et al. (2015). The model architectures used for these studies have the same overall structure as our model and coincide with image–sentence retrieval systems Kiros et al. (2014); Karpathy & Fei-Fei (2015): a pre-trained CNN is fixed or fine-tuned as image feature extractor, followed by a learned transformation, while sentence representations are learned by a randomly initialized recurrent neural network. These models are trained to push the true image–caption pairs closer together, and the false image–caption pairs further from each other, in a joint embedding space.

In addition to learning grounded representations for image–sentence ranking, joint vision and language systems have been proposed to solve a wide range of tasks across modalities such as image captioning Mao et al. (2014a); Vinyals et al. (2015b); Xu et al. (2015), visual question answering Antol et al. (2015); Fukui et al. (2016); Jabri et al. (2016b), text-to-image synthesis Reed et al. (2016) and multi-modal machine translation Libovicky & Helcl (2017); Elliott & Kdr (2017).

Our work is also closely related to multilingual joint representation learning. In this scenario, a single model is trained to solve a task

across multiple languages. Ammar et al. (2016) train a multilingual dependency parser on the Universal Dependencies treebank Nivre et al. (2015) and show that on average the single multilingual model outperforms the monolingual baselines. Johnson et al. (2016) present a zero-shot neural machine translation model that is jointly trained on language pairs $A \leftrightarrow B$ and $B \leftrightarrow C$ and show that the model is capable of performing well on the unseen language pair $A \leftrightarrow C$. Lee et al. (2017a) find that jointly training a many-languages-to-one translation model on unsegmented character sequences improves BLEU scores compared to monolingual training. They also show evidence that the model can handle intra-sentence code-switching. Peters et al. (2017) train a multilingual sequence-to-sequence translation architecture on grapheme-to-phoneme conversion using more than 300 languages. They report better performance when adding multiple languages, even those which are not present in the test data. Finally, massively multilingual language representations trained on over 900 languages have been shown to resemble language families Östling & Tiedemann (2016) and can successfully predict linguistic typology features Malaviya et al. (2017).

In the vision and language domain, multilingual-multimodal sentence representation learning has been limited so far to two languages. The joint training of models on English and German data has been shown to outperform monolingual baselines on image-sentence ranking and semantic textual similarity tasks Gella et al. (2017); Calixto et al. (2017b). Recently Harwath et al. (2018) also showed the benefit of joint bilingual training in the domain of speech-to-image and image-to-speech retrieval using English and Hindi data.

Multilingual grounded learning

We train a standard model of grounded language learning which projects images and their textual descriptions into the same space Kiros et al. (2014); Karpathy & Fei-Fei (2015). The training procedure is illustrated by the pseudo-code in Figure 6.2. Images i are encoded by a fixed pre-trained CNN followed by a learned affine transformation $\psi(i, \theta_\psi)$, and captions c are encoded by a randomly initialized RNN $\phi(c, \theta_\phi)$. The model learns to minimize the distance between pairs $\langle a, b \rangle$ using a max-of-hinges ranking loss Faghri et al. (2017):

$$\begin{aligned} \mathcal{J}(a, b) = \max_{\langle \hat{a}, b \rangle} [\max(0, \alpha - s(a, b) + s(\hat{a}, b))] + \\ \max_{\langle a, \hat{b} \rangle} [\max(0, \alpha - s(a, b) + s(a, \hat{b}))] \end{aligned}$$

where $\langle a, b \rangle$ are the true pairs, and $\langle a, \hat{b} \rangle$ and $\langle \hat{a}, b \rangle$ are all possible contrastive pairs in the mini-batch. The pairs either consists of image-caption pairs $\langle i, c \rangle$, where the model solves a caption-image **c2i** ranking task, or pairs of captions in multiple languages belonging to the same image $\langle c_a, c_b \rangle$, where the model solves a caption-caption **c2c** ranking task Gella et al. (2017). Our monolingual models are trained to minimize the caption-image ranking objective **c2i** on the training set. The multilingual models are trained to minimize the ranking loss for the set of all languages \mathcal{L} in the collection: at each iteration the model is either updated for the **c2i** objective or the caption-caption **c2c** objective given either $\langle c^l, i \rangle$ or a $\langle c_a^k, c_b^m \rangle$ pair in languages $l, k, m, \dots \in \mathcal{L}$. All models are trained by first selecting a task, either **c2i** or **c2c**. In the **c2i** case, a

language is sampled at random followed by sampling a random batch; in the **c2c** case, all possible $< c_a, c_b >$ pairs across all languages are treated as a single data set. All of the model parameters are shared across all tasks and languages.

Implementation. We build our model on the PyTorch implementation² of the VSE++ model Faghri et al. (2017). Images are represented by the 2048D average-pool features extracted from the ResNet50 architecture He et al. (2016b) trained on ImageNet Deng et al. (2009); this is followed by a trained linear layer $\mathbf{W}_I \in \mathbb{R}^{2048 \times 1024}$. Other implementation details follow Faghri et al. (2017): sentences are represented as the final hidden state of a GRU Chung et al. (2014) with 1024 units and 300 dimensional word-embeddings trained from scratch. We use a single word embedding matrix containing the union of all words in all considered languages. The similarity function s in the ranking loss is cosine similarity. We ℓ_2 normalize both the caption and image representations. The model is trained with the Adam optimizer Kingma & Ba (2014) using default parameters and learning-rate of 2e-4. We train the model with an early stopping criterion, which is to maximise the sum of the image–sentence recall scores R@1, R@5, R@10 on the validation set with patience of 10 evaluations. In the monolingual setting the stopping criterion is evaluated at the end of each epoch, whereas in the multilingual setup it is evaluated every 500 iterations. The probability of switching between the **c2i** and **c2c** tasks is set to 0.5. Batches from all data sets are sampled by shuffling the full dataset, going through each batch and re-shuffling when exhausted. The sentence-pair dataset used to

train the **c2c** ranking model for ℓ languages is generated as follows. For a given image i , a set of languages $1 \cdots \ell$, and a set of captions C_1^i, \dots, C_ℓ^i associated with an image i , we generate the set of all possible combinations of size 2 from caption sets \mathcal{C}^i and add the Cartesian product between all resulting pairs $C_m^i \times C_n^i$ in \mathcal{C}^i to the training set.

Experimental setup

Datasets. We train and evaluate our models on the *translation* and *comparable* portions of the Multi30K dataset Elliott et al. (2016b, 2017b). The translation portion (a low-resource dataset) contains 29K images, each described in one English caption with German, French, and Czech translations. The comparable portion (a higher-resource dataset) contains the same 29K images paired with five English and five German descriptions collected independently. Figure 6.1 presents an example of the translation and comparable portions of the data. We used the preprocessed version of the dataset, in which the text is lowercased, punctuation is normalized, and the text is

tokenized³. To reduce the vocabulary size of the joint models, we replace all words occurring fewer than four times with a special “UNK” symbol. Table 6.1 shows the overlap between the vocabularies of the *translation* portion of the Multi30K dataset. The total number of tokens across all four languages is 17,571, and taking the union of the tokens in these four languages results in vocabulary of 16,553 tokens – a 6% reduction in vocabulary size. On the *comparable* portion of the dataset, the total vocabulary between English and German contains 18,337 tokens, with a union of 17,667, which is a 4% reduction in vocabulary size.

Evaluation. We evaluate our models on the 1K images of the 2016 test set of Multi30K either using the 5K captions from the comparable data or the 1K translation pairs. We evaluate on image-to-text ($I \rightarrow T$) and text-to-image ($T \rightarrow I$) retrieval tasks. For most experiments we report Recall at 1 (R@1), 5 (R@5) and 10 (R@10) scores averaged over 10 randomly initialised models. However, in Section 6.6 we only report R@10 due to space limitations and because it has less variance than R@1 or R@5.

Bilingual Experiments

Reproducing Gella et al. (2017)

We start by attempting to reproduce the findings of (Gella et al., 2017). In these experiments we train our multi-task learning model on the *comparable* portion of Multi30K. Our models re-implement their setups used for VSE (Monolingual) and bilingual models Pivot-Sym

Table 6.2: English Image-to-text (I→T) and text-to-image (T→I) retrieval results on the *comparable* part of Multi30K, measured by Recall at 1, 5 at 10. Typewriter font shows performance of two sets of symmetric and asymmetric models from Gella et al. (2017).

(Bilingual) and Parallel-Sym (Bilingual + c2c). The OE, Pivot-Asym and Parallel-Asym models are trained using the asymmetric similarity measure introduced for the order-embeddings Vendrov et al. (2015). The main differences between our models and (Gella et al., 2017) is that they use VGG-19 image features, whereas we use ResNet50 features, and we use the max-of-hinges loss instead of the more common sum-of-hinges loss.

Table 6.2 shows the results on the English comparable 2016 test set. Overall our scores are higher than (Gella et al., 2017), which is most likely due to the different image features ((Faghri et al., 2017) also report a large performance gain when they use the ResNet in-

	VSE	I→T			T→I		
		R@1	R@5	R@10	R@1	R@5	R@10
Symmetric	Pivot-Sym	26.9	56.6	70.0	20.3	46.4	59.2
	Parallel-Sym	28.2	57.7	71.3	20.9	46.9	59.3
	OE	26.8	57.5	70.9	21.0	48.5	60.4
Asymmetric	Pivot-Asym	28.2	61.9	73.4	22.5	49.3	61.7
	Parallel-Asym	30.2	60.4	72.8	21.8	50.5	62.3

Bilingual		35.2	64.3	75.3	24.6	50.8	62.0
+ c2c		37.9	66.1	76.8	26.6	53.0	64.0

Table 6.3: German Image-to-text ($I \rightarrow T$) and text-to-image ($T \rightarrow I$) retrieval results on the *comparable* part of Multi30K, measured by Recall at 1, 5 at 10. Typewriter font shows performance of two sets of symmetric and asymmetric models from Gella et al. (2017).

stead of the VGG image features). Nevertheless, our results show a similar trend to the symmetric cosine similarity models from (Gella et al., 2017): our best results are achieved with bilingual joint training with the added c2c objective. Their models trained with an asymmetric similarity measure show a different trend: the monolingual model is stronger than the bilingual model, and the c2c loss provides no clear improvement.

Table 6.3 presents the German results. Once again, our implementation outperforms (Gella et al., 2017), and this is likely due to the different visual features and max-of-hinges loss. However, our Bilingual model with the additional c2c objective performs the best for

	English		German	
	I→T	T→I	I→T	T→I
Monolingual	56.3	40.1	39.5	20.9
Bi-translation	67.4	55.1	58.3	44.6
+ c2c	58.2	47.7	51.0	39.6
Bi-comparable	67.9	55.7	62.0	48.1
+ c2c	67.6	56.0	61.9	49.1

Table 6.4: R@10 retrieval results on the *comparable* part of Multi30K. Bi-translation is trained on 29K *translation pair* data; bi-comparable is trained by downsampling the *comparable* data to 29K.

German, whereas (Gella et al., 2017) reports the overall best results for the monolingual baseline **VSE**. Their models that use the asymmetric similarity function are clearly better than the Monolingual **OE** model. In general, the results from (Gella et al., 2017) indicate the benefits of bilingual joint training, however, they do not find a clear pattern between the model configurations across languages. In our implementation, we only focused on the symmetric cosine similarity function and found a systematic pattern across both languages: bilingual training improves results on all performance metrics for both languages, and the additional c2c objective always provides further improvements.

Translations vs. independent captions

We now study whether the model can be trained on either translation pairs or independently collected bilingual captions. (Gella et al.,

2017) only conducted experiments on independently collected captions. However, it is known that humans have equally strong preference for translated or independently collected captions of images Frank et al. (2018), which has implications for the difficulty and cost of collecting training data. Our baseline is a Monolingual model trained on 29K single-captioned images in the *translation* portion of Multi30K. The Bi-translation model is trained on both German and English, with shared parameters. Table 6.4 shows that there is a substantial improvement in performance for both languages in the bilingual setting. However, the additional c2c loss degrades performance here. This could be because we only have one caption per image in each language and it is easier to find a relationship between these views of the translation pairs.

In the Bi-comparable setting, we randomly select an English and a German sentence for each image in the *comparable* portion of Multi30K. We only find a minor difference in performance between the Bi-translation and Bi-comparable models for English, but the German results are improved. Crucially, it is still better than training on monolingual data. In the Bi-comparable setting, the c2c loss does not have a detrimental effect on model performance, unlike in the Bi-translation experiment. Overall we find that the *comparable* data leads to larger improvements in retrieval performance.

Overlapping vs. non-overlapping images

In a bilingual setting, we can improve an image-sentence ranking model by collecting more data in a second language. This can be achieved in two ways: by collecting captions in a new language for the same overlapping set of images, or by using a disjoint set of images

	English		German	
	I→T	T→I	I→T	T→I
Full Monolingual	79.8	67.9	74.0	60.5
Half Monolingual	73.7	61.6	66.4	53.9
Bi-overlap	73.6	62.2	67.6	54.9
+ c2c	76.0	65.9	71.2	59.1
Bi-disjoint	73.1	62.1	67.9	54.9

Table 6.5: R@10 retrieval results on the *comparable* part of Multi30K. Full model trained on the 29K images of the *comparable* part, Half model on 14.5K images using random downsampling. For Bi-overlap, both English and German captions are used for 14.5K images. For Bi-disjoint, 14.5K images are used for English and the remaining 14.5K images for German.

and captions in a new language. We compare these two settings here.

In the Bi-overlap condition, we collect captions for the existing images in a new language, i.e. we use all of the English and German captions paired with a random selection of 50% of the images in *comparable* Multi30K. This results in a training dataset of 14.5K images with 145K bilingual captions. In the Bi-disjoint condition, we collect captions for new images in a new language, i.e. we use all of the English captions from a random selection of 50% of the images, and all of the German captions for the remaining 50% of the images. This results in a training dataset on 29K images with a total of 145K bilingual captions.

Table 6.5 shows the results of this experiment. The upper-bound is to train a Monolingual model on the full *comparable* corpus. For the lower bound, we train Half Monolingual models by randomly sam-

pling half of the 29K images and their associated captions, giving 72.5K captions over 14.5K images. Unsurprisingly, the Half Monolingual models perform worse than the Full Monolingual models. In the Bi-overlap experiment, the German model is improved by collecting captions for the existing images in English. There is no difference in the performance of the English model, echoing the results from Section 6.5.1. The Bi-overlap model also benefits from the added c2c objective. Finally, the Bi-disjoint model performs as well as the Bi-overlap model without the c2c objective. (It was not possible to train the Bi-disjoint model with the additional c2c objective because there are no caption pairs for the same image.)

Overall, these results suggest that it is best to collect additional captions in the original language, but when adding a second language, it is better to collect extra captions for existing images and exploit the additional c2c ranking objective.

Multilingual experiments

We now turn our attention to multilingual learning using the English, German, French and Czech annotations in the *translation* portion of Multi30K. We only report the text-to-image ($T \rightarrow I$) R@10 results due to space limitations.

We did not repeat the overlapping vs. non-overlapping experiments from Section 6.5.3 in a multilingual setting because this would introduce too much data sparsity. In order to conduct this experiment, we would have to downsample the already low-resource French and Czech captions by 50%, or even further for multi-way experiments.

Translation vs. independent captions

Table 6.6 shows the results of repeating the translations vs. comparable captions experiment from Section 6.5.2 with data in four languages. The Multi-translation models are trained on 29K images paired with a single caption in each language. These models perform better than their Monolingual counterparts, and the German, French, and Czech models are further improved with the c2c objective. The Multi-comparable models are trained by randomly sampling one English and one German caption from the *comparable* dataset, alongside the French and Czech translation pairs. These models perform as well as the Multi-translation models, and the c2c objective brings further improvements for all languages in this setting.

These results clearly demonstrate the advantage of jointly training on more than two languages. Text-to-image retrieval performance increases by more than 11 R@10 points for each of the four languages in our experiment.

High-to-low resource transfer

We now examine whether the lower-resource French and Czech models benefit from training with the full complement of the higher-resource English and German comparable data. Therefore we train a joint model on the *translation* as well as *comparable* portions of Multi30K, and examine the performance on French and Czech.

Table 6.7 shows the results of this experiment. We find that the French and Czech models improve by 8.8 and 5.5 R@10 points respectively when they are only trained on the multilingual translation pairs (compared to the monolingual version), and by another 2.2 and 2.8 points if trained on the extra 155K English and German *comparable*

	En	De	Fr	Cz
Monolingual	50.4	39.5	47.0	42.0
Multi-translation	58.7	51.2	57.0	51.0
+ c2c	56.3	52.2	55.0	51.6
Multi-comparable	59.2	49.6	57.2	50.8
+ c2c	61.8	52.7	59.2	55.2

Table 6.6: The Monolingual and joint Multi-translation models trained on *translation pairs*, and the Multi-comparable trained on the downsampled *comparable* set with one caption per image.

descriptions. We also find that the additional c2c objective improves the Czech model by a further 4.8 R@10 points (this improvement is likely caused by training the model on 46 possible caption pairs). Our results show the impact of jointly training with the larger English and German resources, which demonstrates the benefits of high-to-low resource transfer.

Bilingual vs. multilingual

Finally, we investigate how useful it is to train on four languages instead of two. Figure 6.3 presents the image-to-text and text-to-image retrieval results of training Monolingual, Bilingual, or Multilingual models. The Monolingual and Bilingual models are trained on a random single-caption-image subsample of the *comparable* dataset with the additional c2c objective, as this configuration provided the overall best results in Sections 6.5.2 and 6.6.1. The Multilingual models are trained with the additional French and Czech *translation* data.

	French	Czech
Monolingual	47.0	42.0
Multilingual	56.3	51.3
+ Comparable	58.9	52.4
+ c2c	61.6	57.2

Table 6.7: Multilingual is trained on all *translation pairs*, + Comparable adds the *comparable* data set.

As can be seen in Figure 6.3, the performance on both tasks and for both languages improves as we move from using data from one to two to four languages.

Conclusions

We learn multilingual multimodal sentence embeddings and show that multilingual joint training improves over bilingual joint training. We also demonstrate that low-resource languages can benefit from the additional data found in high-resource languages. Our experiments suggest that either translation pairs or independently-collected captions improve the performance of a multilingual model, and that the latter data setting provides further improvements through a caption–caption ranking objective. We also show that when collecting data in an additional language, it is better to collect captions for the existing images because we can exploit the caption–caption objective. Our results lead to several directions for future work. We would like to pin down the mechanism via which multilingual training contributes to improved performance for image-sentence ranking. Additionally, we

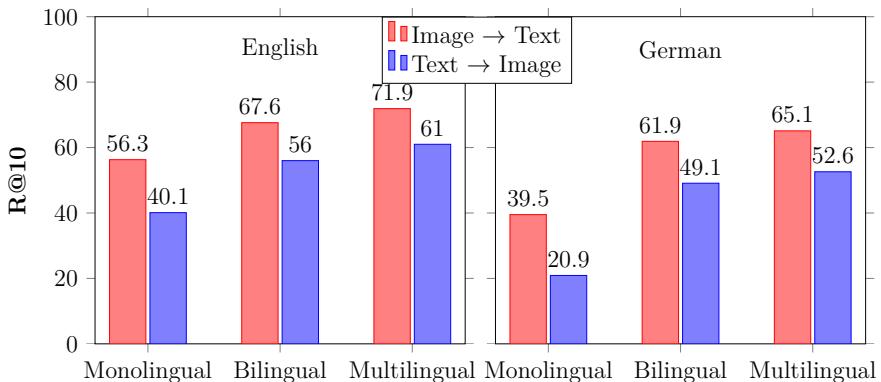

Figure 6.3: Comparing models from the Monolingual, Bilingual and Multilingual settings. The Monolingual and Bilingual models are trained on the downsampled English and German *comparable* sets with additional c2c objective. The Multilingual model uses the French and Czech *translation pairs* as additional data. The results are reported on the full 2016 test set of the *comparable* portion of Multi30K.

only consider four languages and show the gain of multilingual over bilingual training only for the English-German language pair. In future work we will incorporate more languages from data sets such as the Chinese Flickr8K Li et al. (2016c) or Japanese COCO Miyazaki & Shimizu (2016).

Revisiting the Hierarchical Multiscale LSTM

Pre-amble

This Chapter comprises of two parts: 1.) this pre-amble, which gives the reader context about the article and its relationship to the other parts of the thesis and some negative results, 2.) a reproduction study of the Hierarchical Multiscale LSTM (HMLSTM) architecture published at COLING 2018, presented after this pre-amble.

The authors originally aimed at applying the HMLSTM architecture to learning visually grounded representations from the character level. It is a particularly intriguing architecture for the task as it learns interpretable multi-level segmentation of the input string presented left-to-right through discrete boundary variables. However,

we observed a considerable difficulty re-implementing the architecture due to the large degrees of freedom in implementation details. Furthermore, while the HMLSTM does converge on word-level, it does not on character level. This we have found worrying as the comparable three-layer LSTM architecture does converge to a good solution and the original paper by (Chung et al., 2016a) suggests that the HMLSTM should learn tasks that LSTMs learn. Rather, than abandoning the project we have decided to report our image-sentence ranking results here in and include a full Chapter on reproduction instead. In the following article below we raise several points about the importance of reproducibility and verifying claims. Furthermore, we point to general issues when considering complex deep-learning architectures with non-trivial implementation details and training schemes.

Here, let us present our results on image-sentence ranking using the code-base we used for the reproduction experiments. We consider the same task as in Chapters 4, 5 and 6. We learn a joint-embedding space mapping corresponding image-sentence pairs close together. In all experiments we use 1024 hidden units and 300 dimensional word embeddings. Models are optimized with Adam and early stopping using the development set with patience of three epochs. The training-objective is identical to one presented in Chapter 5: it pushes contrastive image i and caption c pairs far from and true pairs close to each other (see Equation 7.1).

	Caption Retrieval				Image Retrieval			
	R@1	R@5	R@10	Med r	R@1	R@5	R@10	Med r
LSTM	38.1	72.7	84.1	2.0	28.8	65.3	79.8	3.0
3-LSTM	38.0	69.6	81.6	2.0	29.5	65.3	80.3	3.0
HMLSTM	34.6	70.3	81.9	3.0	27.1	64.3	78.8	3.0
VSE++	43.6	74.8	84.6	2.0	33.7	68.8	81.0	3.0

Table 7.1: Results on the 1K test-images of COCO on word-level.

$$\begin{aligned} \mathcal{J}(i, c) = & \sum_{\langle \hat{i}, c \rangle} [\max(0, \alpha - s(i, c) + s(\hat{i}, c))] + \\ & \sum_{\langle i, \hat{c} \rangle} [\max(0, \alpha - s(i, c) + s(i, \hat{c}))] \end{aligned}$$

The experiments presented here use the COCO data set with the by now standard splits from Karpathy & Fei-Fei (2015). All models are trained on the training set, early stopping is performed on the developement set and all results are reported on the one thousand image test set. The word-level results are reported in Table 7.1. For comparison we report a comparable state-of-the-art model: VSE++ Faghri et al. (2017). The results show that all architectures get fairly close to the state-of-the-art results on word-level. Furthermore, we inspected the internal dynamics of the HMLSTM and found that the it did learn the desired hierarchical-multiscale dynamics as indicated by the much lower segmentation frequency of the second layer: it segments 0.2% of the times in layer two, which goes up to 14.5% in layer one.

Now let us turn to the character-level results in Table 7.2. The one layer LSTM architecture, as expected, performs considerably worse

	Caption Retrieval					Image Retrieval				
	R@1	R@5	R@10	Med r		R@1	R@5	R@10	Med r	
LSTM	34.2	69.3	80.1	3.0	26.9	62.7	76.6	3.0		
3-LSTM	39.0	71.6	83.5	2.0	30.5	66.8	80.6	3.0		
HMLSTM	0.1	0.3	0.4	2491.0	0.1	0.5	1.0	500.0		

Table 7.2: Results on the 1K test-images of COCO on character-level.

on character-level than on word-level. On the other hand, the architecture with three-layers performs on par with our best word-level model. Lastly, the HMLSTM did not converge. We tried a couple of tricks such as layer-normalization, different learning-rates, residual connections between layers, residual connections over time and more.

This concludes our negative results on character-level image-sentence ranking with the HMLSTM architecture. Using the same code-base comparable architectures reached good performance, while we failed to find a setting where the HMLSTM starts to converge. In the following we present our reproduction study of the HMSLTm architecture as originally applied to language modeling.

Abstract Hierarchical Multiscale LSTM (Chung et al., 2016a) is a state-of-the-art language model that learns interpretable structure from character-level input. Such models can provide fertile ground for (cognitive) computational linguistics studies. However, the high complexity of the architecture, training procedure and implementations might hinder its applicability. We provide a detailed reproduction and ablation study of the architecture, shedding light on some of the potential caveats of re-purposing complex deep-learning architectures. We further show that simplifying certain aspects of the architecture can in fact improve its performance. We also investigate the linguis-

tic units (segments) learned by various levels of the model, and argue that their quality does not correlate with the overall performance of the model on language modeling.

Introduction

Verifying and reproducing claims published in scientific articles is an essential part of building a solid foundation for future research. As such, reproduction has a long history in many scientific fields (Willett et al., 1985; Venables et al., 1993; Waltemath et al., 2011). Recent large-scale studies, however, raise concerns about the reproducibility in a variety of areas and the potential effect of this crisis (Baker, 2016). A reproduction study by the Open Science Collaboration (2015) estimates that only 40% of research in psychology is reproducible, while Begley & Ellis (2012) end up confirming only 11% of preclinical cancer studies. The latter work makes an important link between the low reproducibility rates and the notoriously low impact of preclinical cancer research on clinical practice (Hutchinson & Kirk, 2011).

Our work is motivated by a similar concern, specifically the applicability of complex deep learning architectures for computational (cognitive) linguistics research. State of the art systems often employ complex architectures which integrate various design features and use many optimization techniques. Because the focus is on boosting the final performance on a given task, often little effort is put into understanding where the power of the system comes from. This makes these models much harder to adapt for new tasks or domains. In our view, it is essential not only to be able to reproduce reported results, but also to understand the contribution of various design features through systematic ablation experiments.

The higher performance brought by modern neural network architectures often comes at the cost of our understanding of the representations and structural information the system learns. However, for models to be generalizable to new domains, it is important to move towards analyzing such structural representations, and investigating their impact on the final performance of the model.

In the current study, we examine the reproducibility of a language model with the ability to learn explicit linguistic structure: the Hierarchical Multiscale Recurrent Neural Network (HMLSTM) model. This architecture was introduced by Chung et al. (2016a) and set a new state of the art on language-modeling benchmarks Text8, Hutter Prize and character-level Penn Treebank. Additionally, the paper features examples where the lowest layer of the model recovers word-level segmentation and in some cases performs interpretable morphological analysis. With this reproduction study our motivation is to provide insight into the dynamics of the model, which can facilitate re-using and further developing its architecture and repurposing it for tasks other than language modeling. Crucially, we investigate whether the performance of the model depends on the acquisition of high-quality linguistic structure.

The importance of reproducibility

There is no established tradition of reproduction studies in computational linguistics; however, scattered attempts at reproducing a number of studies have highlighted the importance of investigating the dataset, the model architecture and the evaluation scheme used in experimental designs. For example, Mieskes (2017) quantifies the availability of non-benchmark datasets underlying the experiments.

Horsmann & Zesch (2017) re-run coarse-grained multilingual part-of-speech tagging experiments by Plank et al. (2016) and confirm the superior performance of LSTM-based architectures on fine-grained tagsets. Marrese-Taylor & Matsuo (2017) fail to reproduce the results of three articles in the domain of aspect-based opinion mining, with the conclusion that repeating experiments without the availability of source code is hindered due to lack of details on pre-processing, model architecture specification and exact parameter settings. Morey et al. (2017) replicate the results of 9 discourse parsers trained on the RST Discourse Treebank (RST-DT) (Carlson et al., 2003) and show that most of the recent gains in the domain are due to non-trivial differences in evaluation methodology.

We propose one further step in this direction: in addition to reproducing reported results, it is important to investigate the role the components of complex models play and examine their impact on the behavior of the model. The HMLSTM model that we choose as our case study has many desirable properties. However, it is fairly complex and allows for a considerable degree of freedom for implementation. We experimentally explore the function of architectural details of the HMLSTM model, as well as experiment with varying the specifics of the training procedure. We aim to shed light on the potential bottlenecks involved in re-purposing a complex deep learning sequence modeling architecture for computational linguistics studies.

The importance of interpretability

Language data, both in the form of speech and text, exhibits hierarchical structure: characters or phonemes form morphemes and words, which form phrases, which in turn form whole sentences. At

each level, the units are composed to build up the meaning of the sentence at the highest level. Modern RNN architectures have been very successful in solving character-level NLP tasks (Chung et al., 2016b; Golub & He, 2016; Mikolov et al., 2012). However, they do not make the learned linguistic structure explicit: rather it can be presumed to be cryptically encoded in the states of the hidden layers. The higher performance brought by modern neural network architectures often comes at the cost of our understanding of the representations and structural information such systems learn. However, for a model to be generalizable to new domains, it is important to move towards analyzing such structural representations, and investigating their impact on the final performance of the model.

Understanding the structural information encoded in black-box neural network architectures has been a desired target since Elman (1990) and several studies have used indirect post-analysis techniques and auxiliary tasks to probe the acquired structure. For example, recent studies have assessed the ability of Long Short-Term Memory (LSTM) language models to encode subject-verb agreement (Linzen et al., 2016), analyzed the translation quality of character-level sequence-to-sequence models in terms of several morpho-syntactic grammaticality tests (Sennrich, 2016), Li et al. (2016b) introduce a representation erasure technique to measure the amount of contribution of input words and specific phrases to the decision of RNN-based sentiment classifiers, Kdr et al. (2017) examine the linguistic representations of Gated Recurrent Unit-based architectures for image-sentence ranking, and Chrupaa et al. (2017) and Alishahi et al. (2017) analyze the linguistic structure learned by Recurrent Highway Network models of visually grounded speech understanding.

As an alternative approach, a number of *white-box* architectures have been proposed which learn explicit representations of linguistic structure. For example, Dyer et al. (2016) examine Recurrent Neural Network grammars and analyze its learned syntax (Kuncoro et al., 2016). They conclude that their architecture learns a similar notion of headedness as established head-rule sets and the model learns structure similar to traditional nonterminal categories. Williams et al. (2017a) explore the learned grammars of two state-of-the-art natural language inference models: SPINN (Bowman et al., 2016) and Gumbel Tree-LSTM (Choi et al., 2017). They find that both SPINN and Gumbel Tree-LSTM have close to or worse than chance-level parsing performance on standard benchmarks. Furthermore, they note that in the case of the SPINN architecture the learned structure depends on the tuning of the model and that their findings are different from the SPINN implementation of Yogatama et al. (2016). They further note that consistency of the parses produced by Gumbel Tree-LSTM across multiple runs is not far off chance level.

The Hierarchical Multi-scale LSTM architecture (Chung et al., 2016a) is in the latter class of white-box models. It is designed specifically to allow for learning explicit structure in data: at each layer, it predicts a binary boundary variable at each time-step. These boundaries correspond to an explicit, interpretable segmentation of the input utterance at multiple levels, which can be thought of as different levels of granularity in linguistic structure. At the same time, it reportedly has state-of-the-art performance on several language modeling benchmarks. As such, we believe the model has the potential to impact future computational cognitive linguistics studies. However, it is not clear whether the high performance of this

model demands the acquisition of high-quality linguistic structure from input text. Furthermore, due to the complex architectural design, implementation details might play a large role in the conclusion that can be drawn from the learned structure as in Williams et al. (2017a). We examine the segmentation of the input characters by different versions of this model to see whether their quality impacts the overall performance.

Hierarchical Multiscale LSTM

Let us introduce the notations used throughout this section with the standard LSTM equations:

$$\begin{bmatrix} \mathbf{i}_t \\ \mathbf{f}_t \\ \mathbf{u}_t \\ \mathbf{o}_t \end{bmatrix} = W\mathbf{x}_t + U\mathbf{h}_{t-1} + \mathbf{b} \quad (\text{gates and candidate})$$

$$\mathbf{c}_t = \mathbf{c}_{t-1} \odot \sigma(\mathbf{f}_t) + \tanh(\mathbf{u}_t) \odot \sigma(\mathbf{i}_t) \quad (\text{cell state})$$

$$\mathbf{h}_t = \sigma(\mathbf{o}_t) \odot \tanh(\mathbf{c}_t) \quad (\text{hidden state})$$

The input to an LSTM are the current input \mathbf{x}_t , previous state \mathbf{h}_{t-1} and previous cell state \mathbf{c}_{t-1} . Variables \mathbf{x}_t and \mathbf{h}_{t-1} are used to compute the input gate \mathbf{i}_t , forget gate \mathbf{f}_t , candidate activation \mathbf{u}_t and output gate \mathbf{o}_t . In the second equation \mathbf{f}_t and \mathbf{i}_t are used to trade off the candidate activation \mathbf{u}_t and the previous cell-state \mathbf{c}_{t-1} using the element-wise multiplication \odot . This results in the current cell state \mathbf{c}_t . Finally, the output gate soft-selects the components of $\tanh(\mathbf{c}_t)$ to write to the hidden state \mathbf{h}_t . The function σ refers to the sigmoid

function.

HMLSTM – To make the explanation of the HMLSTM architecture more straight-forward, let us first consider the bottom- and top-layer as they are special cases of any ℓ -th layer. In addition, we provide vectorized version equations of the HMLSTM architecture which allow for batch sizes larger than 1 (see Appendix .1).

Bottom Layer – The bottom layer of the HMLSTM takes as input: 1) *bottom-up connection*: input at the current time-step \mathbf{x}_t ; 2) *recurrent connection*: hidden and cell states $\langle \mathbf{h}^1_{t-1}, \mathbf{c}^1_{t-1} \rangle$ and previous boundary variable z_{t-1}^1 from $\ell = 1$; and 3) *top-down connection*: hidden state \mathbf{h}^2_{t-1} from $\ell = 2$. It outputs the state tuple $\langle \mathbf{h}_t^1, \mathbf{c}_t^1 \rangle$ and boundary variable z_t^1 .

$$\begin{bmatrix} \mathbf{i}_t \\ \mathbf{f}_t \\ \mathbf{u}_t \\ \mathbf{o}_t \\ z_t \end{bmatrix} = W\mathbf{x}_t + U\mathbf{h}_{t-1}^1 + z_{t-1}V\mathbf{h}_{t-1}^2 + \mathbf{b} \quad (7.1)$$

The activation function on z_t is the hard-sigmoid followed by the rounding operation to discretize it to $\{0, 1\}$: $z_t := \text{round}(\text{hard_sigmoid}(z_t))$. The top-down connection is turned on and off by z_{t-1} . When the layer detects a boundary in the previous step (i.e. $z_{t-1} = 1$), takes context from the higher layer through the top-down connection. After computing the activations the layer either runs a regular LSTM UPDATE or does a FLUSH of its input:

$$\mathbf{c}_t = \begin{cases} \mathbf{c}_{t-1} \odot \sigma(\mathbf{f}_t) + \tanh(\mathbf{u}_t) \odot \sigma(\mathbf{i}_t) & \text{if } z_{t-1} = 0 \text{ (UPDATE)} \\ \tanh(\mathbf{u}_t) \odot \sigma(\mathbf{i}_t) & \text{if } z_{t-1} = 1 \text{ (FLUSH)} \end{cases} \quad (7.2)$$

The final hidden state is given by the regular LSTM update $\mathbf{h}_t = \sigma(\mathbf{o}_t) \odot \tanh(\mathbf{c}_t)$.

Top Layer – The top layer has both bottom-up $\mathbf{h}_t^{\ell-1}, z_t^{\ell-1}$ and recurrent connections $< \mathbf{h}_t^{\ell-1}, \mathbf{c}_t^{\ell-1} >$, but no top-down connection. At each step, it outputs the state tuple $< \mathbf{h}_t^\ell, \mathbf{c}_t^\ell >$:

$$\begin{bmatrix} \mathbf{i}_t \\ \mathbf{f}_t \\ \mathbf{u}_t \\ \mathbf{o}_t \end{bmatrix} = z_t^{\ell-1} W \mathbf{h}_t^{\ell-1} + U \mathbf{h}_{t-1}^\ell + b \quad (7.3)$$

The bottom-up input $\mathbf{h}_t^{\ell-1}$ is gated by $z_t^{\ell-1}$. When $z_t = 1$ the higher layer takes one step and performs UPDATE; otherwise it ignores the current time-step and performs COPY:

$$\mathbf{c}_t = \begin{cases} \mathbf{c}_{t-1} \odot \sigma(\mathbf{f}_t) + \tanh(\mathbf{u}_t) \odot \sigma(\mathbf{i}_t) & \text{if } z_t = 1 \text{ (UPDATE)} \\ \mathbf{c}_{t-1} & \text{if } z_t = 0 \text{ (COPY)} \end{cases} \quad (7.4)$$

Middle layers – The general HMLSTM layer runs all operations: UPDATE, COPY and FLUSH. It takes as input 1) *bottom-up connection*: lower layer state $\mathbf{h}_t^{\ell-1}$ and boundary variable $z_t^{\ell-1}$; 2) *recurrent connection*: hidden and cell states $< \mathbf{h}_t^{\ell-1}, \mathbf{c}_t^{\ell-1} >$ and boundary vari-

able z_{t-1}^ℓ ; and 3) *top-down connection*: hidden state $\mathbf{h}_{t-1}^{\ell+1}$. It outputs the tuple $\langle \mathbf{h}_t^\ell, \mathbf{c}_t^\ell \rangle$ and boundary variable z_t^ℓ :

$$\begin{bmatrix} \mathbf{i}_t \\ \mathbf{f}_t \\ \mathbf{u}_t \\ \mathbf{o}_t \\ z_t \end{bmatrix} = z_t^{\ell-1} W \mathbf{h}_t^{\ell-1} + U \mathbf{h}_{t-1}^\ell + z_{t-1}^\ell V \mathbf{h}_{t-1}^{\ell+1} + b \quad (7.5)$$

The bottom-up connection is masked by $z_t^{\ell-1}$ as in the top-layer, while the top-down connection is masked by z_{t-1}^ℓ as in the bottom-layer. The variables $z_t^{\ell-1}$, z_{t-1}^ℓ determine which of the three operations the cell runs. FLUSH is executed if the layer detects a boundary in the previous step (i.e. $z_{t-1}^\ell = 1$). If this is not the case and the lower layer does not detect a boundary, the layer runs COPY. However, if the lower layer does detect a boundary $z_{t-1}^{\ell-1}$, it runs UPDATE:

$$\mathbf{c}_t = \begin{cases} \tanh(\mathbf{u}_t) \odot \sigma(\mathbf{i}_t) & \text{if } z_{t-1}^l = 1 \text{ (FLUSH)} \\ \mathbf{c}_{t-1} & \text{if } z_{t-1}^\ell = 0 \text{ and } z_t^{\ell-1} = 0 \text{ (COPY)} \\ \mathbf{c}_{t-1} \odot \sigma(\mathbf{f}_t) + \tanh(\mathbf{u}_t) \odot \sigma(\mathbf{i}_t) & \text{if } z_{t-1}^\ell = 0 \text{ and } z_t^{\ell-1} = 1 \text{ (UPDATE)} \end{cases} \quad (7.6)$$

Output gate – The output embedding \mathbf{h}_t^e of the HMLSTM is computed by the following gating mechanism:

$$g_t^\ell = \sigma(\mathbf{w}_\ell^T [\mathbf{h}_1; \mathbf{h}_2; \mathbf{h}_3]) \quad (7.7)$$

$$\mathbf{h}_t^e = \text{ReLU}(g_t^\ell W_\ell^e \mathbf{h}_t^\ell) \quad (7.8)$$

It takes states from the three layers and computes a gating value for each g_t^1, g_t^2 and g_t^3 using the parameter vector \mathbf{w}^ℓ . These scalars are used to weight the $W_l^e \mathbf{h}_t^l$ for each layer where W_ℓ^e is a learned parameter. It is important to add some mechanism to combine the activations of the three layers for language modeling as all three layers tick on a different time-scale, but the network has to generate an output at each time-step. This combined embedding \mathbf{h}_t^e is then used in the final softmax layer to predict the probability distribution over the next character.

Experiments

Experimental setup

Upon our request, the authors of the original paper shared a code base with us implementing the HMLSTM architecture and functionality to run the experiments on Penn Treebank (henceforth PTB). The code was implemented in Tensorflow version 1.1 (Abadi et al., 2016), which we ported with minimal modifications to version 1.6 to be able to run it on our system. In the default settings, the code contains ℓ^2 -norm weights penalty term with a coefficient of 0.0005, which we also kept fixed across experiments. Furthermore, the given source code has a special initialization strategy used for the weights matrices: until the last column vector it is initialized with orthogonal initialization with

standard normal distribution. The last column vector (corresponding to the logit of z) is initialized with Glorot uniform initialization with $\sigma = \sqrt{\frac{6.0}{\text{fanin} + \text{fanout}}}$. Due to no initialization details in the original paper we used the initialization defaults provided in the code base for all PTB and Text8 experiments. Lastly, the authors did not refer to publicly available pre-processed versions of the datasets and we used our versions following the details of the paper. We made the following changes to the original code:

Baseline – The authors report LSTM baselines for both PTB and Text8 data sets. The exact configuration of the baseline is not discussed in the paper, however, the authors do share that they implement both layer-normalization and the output module. We train a three-layer stacked LSTM with the same hyperparameters as the HMLSTM.

Layer normalization – The original paper reports results using layer normalization (Ba et al., 2016), which was not implemented in the code base. There are multiple options where to apply it in the case of a LSTM cell. For the HMLSTM cell we implemented it based on equations 20-22 in the paper introducing the technique (Ba et al., 2016). Furthermore, we applied layer-norm to the input and output embedding layers since the performance of the model was found to be unstable otherwise.

Learning-rate schedule and early-stopping – The code base did not include an implementation of the learning-rate schedule that was reported to be used in the original experiments. The learning-rate schedule reported in the paper divides the learning rate by 50 when no improvement is observed in the validation

loss. In our code we monitor the validation loss at each epoch. The original code base ran the models for 500 epochs with no early-stopping and no learning-rate schedule, however, we use early stopping with patience of 4 as very small improvements are observed after reducing the learning rate four times by 50.

Evaluation – We report the bits-per-character (bp_c) of the trained models by computing the entropy (in base 2) of the entire test set and dividing it by the number of characters. The code did not implement the evaluation procedure and we have not found the exact details in the paper. Our implementation follows Mikolov et al. (2012): we use batch size of 1 and carry the states of the recurrent model over to the following batch of 100 characters until the whole test sequence is processed.

The experimental results reported in Section 7.5 are all using this revised implementation, manipulating various ablation factors as described in Section 7.4.2. Following Chung et al. (2016a), we report results on the following two datasets.

Character-level Penn Treebank – The smaller-scale experiments apply variations of the model on the Penn Treebank dataset (Marcus et al., 1993) using the splits and preprocessing from Mikolov et al. (2012). All models are trained with sequence lengths of 100 and batch size of 64. Before each epoch the dataset is randomly cropped to be divisible by 100. The parameters are optimized with Adam (Kingma & Ba, 2014) with initial learning rate of 0.002, which is divided by 50 if no improvement on the validation data is observed after a full epoch. The norm of the gradient is clipped at 1.0. For all models we

use 512 units for all layers and 128 dimension character embeddings as reported in the paper.

Text8 – The Text8 dataset (Mahoney, 2011) is extracted from Wikipedia and is a sequence of 100 million alphabetical characters and spaces. The splits used by Chung et al. (2016a) correspond to the (by now standard) splits introduced in Mikolov et al. (2012): first 90M characters for training, the next 5M for validation and the final 5M characters for testing. On this dataset models are trained on sequence length of 100 and batch size of 128. The initial learning rate of Adam was set to 0.001 and we applied the learning-rate schedule and early-stopping strategy described before. The norm of the gradient is clipped at 1.0. We use 1024 units for the HMLSTM layers and 2048 output embedding units.

Like in the original paper, models are trained to minimize the log-likelihood of the training set and the non-differentiability gap caused by the rounding operation when discretizing the boundary variables is solved by using the straight-through estimator (Bengio et al., 2013b).

Ablation factors

In order to analyze the behavior of the model and the impact of its various architectural design features as well as evaluation settings, we manipulate the following factors in our experiments.

Layer normalization (LN). As mentioned in the previous section, there was a mismatch between the description of the HMLSTM model in Chung et al. (2016a) and the code base provided to us in terms of layer normalization. Therefore we report our experimental results both with and without layer normalization.

Learning-rate schedule (Schedule). Similarly, the paper and the code base do not match in applying learning-rate schedule, therefore we report results with and without scheduling.

Sensitivity to slope (α). Hard-sigmoid (Gulcehre et al., 2016) is a piecewise linear approximation of the sigmoid function, defined as the first-order Taylor expansion of the sigmoid around $x \approx 0$ and clipped between the limits of the original function (0 and 1): $\max(0, \min(1, 0.25x + 0.5))$; where 0.25 is the slope α . The authors describe the slope annealing trick for the PTB experiments and state that they start from slope 0.5 and slowly increase it at maximum until 2.5. We have not found details regarding the α values in other experiments, but used the default $\alpha = 0.5$ in the code-base. We test whether the hard-sigmoid slope $\alpha = 0.25$ reaches the same performance as the specific choice of $\alpha = 0.5$. Furthermore, we gauge sensitivity to α using values 0.125 and 1.0.

COPY operation on the last layer (CopyLast). The code base by default, only applies the COPY operation at the last layer on the cell state \mathbf{c}_t^l , but not on the hidden state \mathbf{h}_t^l . In the latter case if the layer runs COPY it takes the previous cell state and applies the new output gate on it along with the tanh function $\mathbf{o}_t \odot \tanh(\mathbf{c}_{t-1})$. This is different from the original formulation of the HMLSTM. The main experiments were run with this default, but we also report the impact of changing this parameter.

Top-down connection (NoTopDown). When the HMLSTM cell runs the FLUSH operation, it computes the new cell-state by $\mathbf{i}_t \odot \mathbf{u}_t$ and the previous cell-state is dropped from the compu-

tation. However, both \mathbf{i}_t and \mathbf{u}_t depend on the previous state \mathbf{h}_{t-1} . As such, information from the past steps still “leaks” even at FLUSH and each layer can potentially retain enough information for future computations without the use of top-down connections. In our experiments we run the HMLSTM model with and without top-down input to evaluate the impact of this simplification.

Simpler output layer (SimplerOut). The hidden state of the last layer of the HMLSTM is not updated at every time-step and as such it computes a gated embedding combining the representation of all three layers to be able to provide a prediction for every time-step. Here we implement a simplification to the output layer by replacing it with a single affine transformation, embedding the concatenated hidden states: $\mathbf{h}_t^e = \text{ReLU}(W^e[\mathbf{h}_1; \mathbf{h}_2; \mathbf{h}_3])$.

Alternative architecture (HMRNN). One of the motivations for the HMLSTM architecture in the original paper (Chung et al., 2016a) is that the hierarchical multiscale structure might help with the vanishing gradient problem as gradients are back-propagated through fewer time-steps. Here we introduce an alternative architecture that we call HMRNN, which replaces the LSTM updates with simple Elman RNN recurrence. It is a much simpler model and it helps in understanding if the hierarchical multi-scale structure itself is enough to alleviate the vanishing gradient problem, or if the LSTM-style updates are essential for the good performance.

	PTB	Text8
HMLSTM reported by (Chung et al., 2016a)	1.25	1.29
3-layer LSTM reported by (Chung et al., 2016a)	1.29	1.39
3-layer LSTM + Schedule + LN	1.32	1.37
HMLSTM + Schedule + LN	1.27	1.36
HMLSTM + Schedule + LN + CopyLast	1.29	1.36

Table 7.3: Reproducing language modeling results (in bpc) on PTB and Text8 datasets.

$$\mathbf{h}_t = \begin{cases} \tanh(W\mathbf{h}_t^{l-1} + V\mathbf{h}_{t-1}^{l+1}) & \text{if } z_{t-1}^l = 1 \text{ (FLUSH)} \\ \mathbf{h}_{t-1} & \text{if } z_{t-1}^l = 0 \text{ and } z_t^{l-1} = 0 \text{ (COPY)} \\ \tanh(W\mathbf{h}_t^{l-1} + U\mathbf{h}_{t-1}^l) & \text{if } z_{t-1}^l = 0 \text{ and } z_t^{l-1} = 1 \text{ (UPDATE)} \end{cases} \quad (7.9)$$

The HMRNN architecture implements a simple formulation of the hierarchical multiscale intuition. In case of the FLUSH operation, it only takes as input the hidden state of the lower layer and the hidden state of the higher layer at the previous step. In case of COPY it just uses the previous hidden state. Finally, when running UPDATE it applies the simple Elman network update. See Appendix .2 for a vectorized implementation.

Experimental Results

Reproducing language modeling results

We attempt to replicate the language modeling experiments of Chung et al. (2016a) on the character level Penn Treebank and Text8 datasets.

Table 7.3 shows the language modeling results reported by Chung et al. (2016a) on both datasets. It also reports results of our reproduction of the original experiments as described in the paper. This means using the HMLSTM architecture with layer normalization on all layers, and with learning-rate scheduling. Since the use of the COPY operation on the last layer is ambiguous and not consistent between the original paper and the code base, we report results both with COPY on and off.

Our most faithful reproduction of the original experiments, which uses the HMLSTM architecture with learning-rate schedule, layer normalization and COPY on the last layer, results in 1.29 bpc on the PTB dataset. Dropping the COPY option improves the results to 1.27 bpc, which is still below the results reported in Chung et al. (2016a) on the same dataset (1.25). Our 3-layer LSTM baseline on PTB also under performs the baseline reported by Chung et al. (2016a)(1.32 compared to 1.29 bpc).

On the Text8 dataset, our results (1.36) are much further from the published ones (1.29), with the HMLSTM performing very close to the 3-layer LSTM baseline (1.37). We did not pursue further experiments on this dataset. The discrepancy could be due to the fact that the script that the authors shared with us was optimized for PTB, and some of the settings might need to be changed for Text8. However, since we have not found such differences reported in the paper, we used the same setting for both datasets. Interestingly, contrary to the HMLSTM results, our implementation of the 3-layer LSTM basline improves the reported baseline performance from 1.39 to 1.37 bpc.

Ablation results

		BPC	Iter.	z^1	z^2	z -rat
1	HMLSTM + Schedule + LN + copylast	1.29	10K	0.41	0.25	1.6
2	HMLSTM	1.39	16K	0.23	0.15	1.5
3	HMLSTM + Schedule	1.32	12K	0.25	0.16	1.5
4	HMLSTM + Schedule + LN	1.27	12K	0.42	0.09	4.6
5	HMLSTM + Schedule + LN + $\alpha=0.125$	1.28	14K	0.41	0.23	1.7
6	HMLSTM + Schedule + LN + $\alpha=0.25$	1.27	12K	0.31	0.21	1.4
7	HMLSTM + Schedule + LN + $\alpha=1.0$	4.32	4K	1.0	1.0	1.0
8	NoTopDown + Schedule + LN	1.28	12K	0.64	0.28	2.2
9	SimplerOutput + Schedule + LN	1.25	10K	0.64	0.31	2.0
10	3-layer LSTM + Schedule + LN	1.32	9K	N/A	N/A	N/A
11	3-layer LSTM + Schedule + LN + SimplerOut	1.26	12K	N/A	N/A	N/A
12	HMRNN + Schedule + LN	1.40	18K	0.0	1.0	0.0

Table 7.4: Ablation results on PTB

Since we did not succeed in reproducing the original results on Text8, we only perform the ablation experiments on the PTB dataset. Table 7.4 summarizes the results of these experiments. On the first row, we repeat our reproduction results using the most faithful replication of the original experiments (HMLSTM + Schedule + LN + CopyLast). We will compare the results from various modifications of the architecture or evaluation setup to these base results.

Layer normalization and learning-rate schedule – As is evident from the results on rows 2–4, adding learning-rate schedule and layer normalization improve the results over the base HMLSTM. Furthermore, the results on row 4 (HMLSTM + Schedule + LN) are better than the reproduction results which also implement the

CopyLast feature. Therefore, in the rest of the experiments, we consistently add layer normalization on all layers as well as learning-rate scheduling, and drop CopyLast.

Sensitivity to alpha – Rows 5–7 show results for different values of the slope α . Using the by definition hard-sigmoid slope $\alpha = 0.25$ instead of the default $\alpha = 0.5$ in the code does not degrade the performance. Lowering alpha to $\alpha = 0.125$ degrades the performance slightly. Since Chung et al. (2016a) mention that they increase the slope up to $\alpha = 2.5$, we also tested the results with a higher value of $\alpha = 1.0$ (row 7), which caused the model to diverge after 4,000 iterations.

Architectural modification: top-down connection and simpler output – Interestingly, as can be seen from row 8, removing the top-down connections (and keeping the model structure fixed otherwise) only degrades the performance by a small margin; from 1.27 bpc to 1.28. Even more surprising is the effect of using a simpler output layer: replacing the gated-output layer by our simple output module improves the results from 1.27 to 1.25. This, in fact, is the best results we have achieved. Similarly rows 10 and 11 show that the simpler output layer improves the baseline 3-layer LSTM performance from 1.32 bpc to a competitive 1.26 bpc.

Alternative architecture: HMRNN – The simplified architecture which replaces the LSTM updates with Elman RNN produces results that are much worse (1.40) than the HMLSTM counterpart (1.27). Our ablation experiments show that using layer normalization and learning-rate schedule is beneficial, high values for the slope of

the sigmoid function hurt performance, but the model performance is robust otherwise to smaller α values. The LSTM updates are essential for good performance of the HMLSTM model. Finally, simplifying certain aspects of the model such as removing the top-down connection might not hurt much, and in other cases such as simplifying the output layer it can actually enhance the overall performance.

Segmentation results

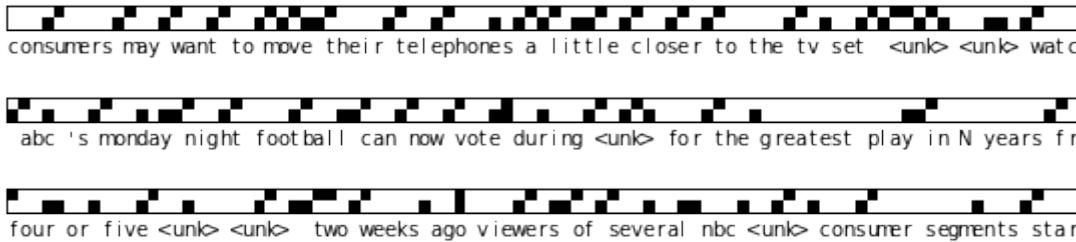

Figure 7.1: Segmentation examples. Black means $z_t = 1$, white $z_t = 0$.

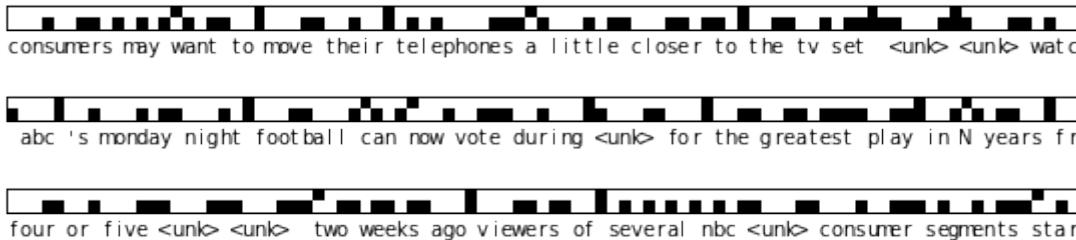

Figure 7.2: Segmentation examples with layer normalization. Black means $z_t = 1$, white $z_t = 0$.

The HMLSTM model predicts binary boundary variables z_t^1 and z_t^2 at each time-step, which correspond to a segment of the input

utterance at each level. The frequencies of z_t^1 and z_t^2 provide a high-level description of segmentation properties of the network and are reported in Table 7.4. Based on the hierarchical multiscale intuition, the expected behavior is that the z_t^1 frequency is higher than z_t^2 as the former corresponds to words or morpheme-like units, whereas the latter corresponds to larger chunks. The ratio of z_t^1 to z_t^2 frequencies is reported in the last column of Table 7.4.

Running the HMLSTM default configuration with added layer-normalization and learning-rate schedule results in the largest separation in the time-scale of the layers as indicated by the z -ratio of 4.67. Interestingly, only changing the α value to 0.125 or 0.25 results in a much narrower gap (1.78 and 1.48 respectively), without a big impact on bpc. Furthermore, the HMLSTM with schedule, layer-norm and $\alpha = 0.125$ in row 5 performs on the same level as our NoTopDown ablation architecture, with a smaller z -ratio.

The segmentation examples reported in the original paper show the first layer of the HMLSTM segmenting the sequence at word boundaries (i.e. spaces), and the higher layer segments corresponding to multi-word chunks. Figure 7.1 shows segmentation results of the HMLSTM with learning-rate schedule and Figure 7.2 with the added layer normalization. Our runs could not reproduce the segmentation results visualized in the original paper and overall we do not find a relationship between the performance of the model and segmentation behavior.

Conclusion

In our attempt to reproduce the results in Chung et al. (2016a) we re-ran the HMLSTM model on two datasets: PTB and Text8. On PTB

the final performance of the model almost matches the original results, but not quite. Our best result was achieved by a slight modification to the COPY operation of the last-layer provided in the source-code, but not detailed in the paper and with our added simplification to the output layer.

We could not reproduce the results on Text8 using the same code base received from the authors. This might be due to the non-availability of the pre-processed version of the dataset. Another potential source might be the lack of detail in the paper on the initialization scheme and weight penalty, which led us to keep these implementation details constant across datasets. Furthermore, the layer normalization might have been implemented on different layers across different datasets. We have made several attempts until reaching the conclusion that it needs to be implemented on every layer of the HMLSTM. This was found to perform best on PTB, but might not be the best setting for Text8. Similarly, the learning-rate schedule was applied based on the monitoring of the loss after every epoch, but this was an informed guess.

Two simplifications were applied to the architecture successfully: 1) removing top-down connections only slightly degraded performance, and 2) simplifying the output layer improved performance in our experiments. There is space for possible modifications that fell out of the scope of the current work like applying REINFORCE gradients in place of the straight-through estimator.

We could not reproduce the segmentation results provided in the paper. Furthermore, we did not observe a close relationship between the segmentation behavior and the final performance. Changing the slope variable α to 0.25 from 0.5, while keeping all other details con-

stant, resulted in the same performance, but huge difference in segmentation behavior.

The observations made here are not specific to the work of Chung et al. (2016a) and the HMLSTM architecture. Similar results have been reported recently by Williams et al. (2017a), whose re-implementation of the considered architecture did not produce the reported performances. One of their considered models learned a qualitatively different latent structure than another re-implementation by Yogatama et al. (2016) and the other architecture did not converge to the same structure across runs. The HMLSTM architecture was considered for reproduction due to its intriguing property of learning interpretable structure from character-level input. The detailed reproduction and ablation study was provided to surface some of the potential difficulties that can hinder the applicability of such models for future studies.

Vectorized formulation of the HMLSTM

Here are the vectorized equations for the bottom, middle and top layers of the HMLSTM. Note, the computation process should be executed from top to bottom and left to right when there are multiple equations.

Bottom layer

$$\mathbf{c}_t = (1 - z_{t-1})\mathbf{c}_{t-1} \odot \sigma(\mathbf{f}_t) + \tanh(\mathbf{u}_t) \odot \sigma(\mathbf{i}_t) \quad (10)$$

Top layer

$$\begin{aligned} \hat{\mathbf{c}}_t &:= \mathbf{c}_{t-1} \odot \sigma(\mathbf{f}_t) + \tanh(\mathbf{u}_t) \odot \sigma(\mathbf{i}_t) & \hat{\mathbf{h}}_t &:= \sigma(\mathbf{o}_t) \odot \tanh(\mathbf{c}_t) \\ \mathbf{c}_t &:= z_t \hat{\mathbf{c}}_t + (1 - z_t) \mathbf{c}_{t-1} & \mathbf{h}_t &:= z_t \hat{\mathbf{h}}_t + (1 - z_t) \odot \mathbf{h}_{t-1} \end{aligned} \quad (11)$$

Middle layer

$$\begin{aligned} c_m &= (1 - z_{t-1}^\ell)(1 - z_t^{\ell-1}) & \mathbf{c}_t &= \mathbf{u}_g + c_m(\mathbf{c}_{t-1} - \mathbf{u}_g) + u_m(\sigma(\mathbf{f}_t) \odot \mathbf{c}_{t-1}) \\ u_m &= (1 - z_{t-1}^\ell)z_t^{\ell-1} & \mathbf{h}_t &:= \sigma(\mathbf{o}_t) \odot \tanh(\mathbf{c}_t) \\ \mathbf{u}_g &= \sigma(\mathbf{i}_t) \odot \tanh(\mathbf{u}_t) & \mathbf{h}_t &:= c_m \mathbf{h}_t + c_m \odot \mathbf{h}_{t-1} \end{aligned} \quad (12)$$

Variables c_m , u_m and \mathbf{u}_g stand for copy-mask, update-mask and gated-candidate activation respectively.

Vectorized formulation of the HMRNN

Here are the vectorized equations for the bottom, middle and top layers of the HMRNN. Note, the computation process should be executed from top to bottom and left to right when there are multiple equations.

Bottom layer

$$\mathbf{h}_t = \tanh(W\mathbf{x}_t + (1 - z_{t-1}^l)U\mathbf{h}_{t-1}^l + z_{t-1}^l \times V\mathbf{h}_{t-1}^{l+1}) \quad (13)$$

Top layer

$$\mathbf{h}_t = (1 - z_t^{l-1}) \times \mathbf{h}_{t-1} + z_t^{l-1} \times \tanh(W\mathbf{x}_t + U\mathbf{h}_{t-1}^l) \quad (14)$$

Middle layer

$$\begin{aligned} c_m &= (1 - z_{t-1}^\ell)(1 - z_t^{\ell-1}) & h_f &= W\mathbf{h}_t^{l-1} + V\mathbf{h}_{t-1}^{l+1} \\ u_m &= (1 - z_{t-1}^\ell)z_t^{\ell-1} & h_u &= W\mathbf{h}_t^{l-1} + U\mathbf{h}_{t-1}^l \\ \mathbf{h}_t &= c_m \mathbf{h}_{t-1} + (1 - c_m) \tanh((1 - u_m)h_f + u_m h_u) \end{aligned} \quad (15)$$

Variables c_m and u_m stand for copy-mask and update-mask activation respectively.

A

Conclusion and discussion

Traditional techniques to learn representations of words and sentences only consider linguistic context as a source of information and focus on the representation of a single language. The aim of this thesis was to study make advances towards learning and understanding *visually grounded* and *multilingual* representations. This final chapter is dedicated not only to briefly summarize our main findings, but also to point to some of the limitations and implications of our work.

Visually grounded word representations

The starting point of the thesis is visual grounding on the word level for a single language. Chapter 3 is dedicated to learning word-representations based on the co-occurrences between words and high-level image features. We implemented a model taking inspiration

from the cross-situational account to word acquisition; a framework of lexical development based on the process of children repeatedly being exposed to pairs of linguistic utterances and perceptual stimuli. Throughout this process they learn a mapping between linguistic units and their referents updating their hypothesis based on a stream of co-occurrence statistics between modalities as evidence. There has been a large number of experimental studies showing that children use cross-situational evidence for word learning to learn this mapping fast (Smith & Yu, 2008) and under a high level of *referential uncertainty* (Vouloumanos & Werker, 2009).

We depart in two major ways from the canonical computational cross-situational models (Siskind, 1996; Fontanari et al., 2009; Fazly et al., 2010a; Kachergis et al., 2012; Matusevych et al., 2013; Yu & Siskind, 2013): 1.) we use large image–description benchmark data sets developed for machine learning purposes, which naturally presents a high level of referential uncertainty and ambiguity 2.) take continuous image representations rather than artificial symbolic scene descriptors. More concretely approach adapts the cross-situational word learning model of (Fazly et al., 2010a), which is an online version of the IBM Model 1. word-translation model (Brown et al., 1993) to take continuous image features to represent scenes coming from pre-trained convolutional neural networks. Even more unorthodox in the cross-situational literature our model does not learn a mapping between words and objects (Fazly et al., 2010a; Lazaridou et al., 2016), but the strength of the relationship between words and high-level global image feature descriptors. As such our main experimental protocol is related departs from the standard word-object retrieval evaluation performed on the CHILDES data set (Goodman et al.,

2008; Kievit-Kylar et al., 2013; Lazaridou et al., 2016) and is more similar to performing image–tagging (Weston et al., 2010). Through these retrieval experiments we find that our model tags images with relevant concepts.

In another experiment we measure the correlation between word similarities under our model and according to human participants and compare the results to state-of-the-art distributional model trained on the same sentences. Word-similarity benchmark experiments originate from (Rubenstein & Goodenough, 1965) who intended to provide empirical evidence for the distributional hypothesis of (Harris, 1954). Later they became standard in comparing various approaches of computational using such similarity judgements (Faruqui & Dyer, 2014).¹ Using this protocol allows us to directly compare a cross-situational and visually grounded computational model of child word learning to the state of the art distributional word2vec approach of the time. The models perform on the same level, however, more interestingly by creating *abstract* and *concrete* portions of word similarity benchmarks we find that the distributional word2vec is better on the *abstract*, while the cross-situational model on the *concrete* set.

The first main result of Chapter 3 is that our cross-situational word learning model learns meaningful word representations as demonstrated by our image–word matching experiments. Secondy, we train a distributional model and our visually grounded model on the same same sentences; the former learning word representations from linguistic the second from visual contexts. They perform on a similar level in terms of approximating human similarity judgements, however, the visual context is more informative in the case of concrete

¹That said many problems with the validity and consistency of this methodology have been raised around that time (Faruqui et al., 2016).

words, whereas distributional cues are more helpful for learning the meaning of abstract words. Our result highlights the complementarity between these different sources of learning signals.

Note, however, that even though our algorithm introduced in Chapter 3 is incremental and is based on well established models of word-learning (Fazly et al., 2010a) it is not intended as a complete account of child lexical development e.g.: consider the lack of integration of social cues or parent directed attention, both of which have been shown to boost learning in children (Gleitman, 1990; Tomasello & Akhtar, 1995) and in computational models of cross situational models of word learning (Yu & Ballard, 2007; ?).

Visually grounded sentence representations

Moving from representations of words to full sentences in Chapter 4 we continued our comparative study between distributional and visually grounded representations. Concretely, in Chapter 4 we analyze the patterns of hidden activations of our recurrent visually grounded sentence representations learning model **IMAGINET** (Chrupała et al., 2015a). This architecture consists of two separate gated recurrent unit networks coupled through a shared word embedding matrix. The **VISUAL** pathway performs visually grounded learning through the image–sentence ranking objective, while **TEXTUAL** is trained as a language model to maximize the likelihood of the following word given the history.

In (Chrupała et al., 2015a) we compare the word representations learned by only training one of the subnetworks as compared to training them jointly and find that the word-similarity judgements of **VISUAL** correlate better with human similarity judgements than

TEXTUAL and that the joint **MultiTask** model is superior to both. On the task of image–sentence ranking **VISUAL** outperforms our bag-of-words-baseline, but by a large margin. This led us to test whether the **VISUAL** trained on caption with randomly permuted word order can perform on equal level to it trained on the original captions. We find that the model trained on the original captions does perform better suggesting that it successfully exploit word order information.

Chapter 4 is dedicated to a more in depth investigation of the kind of linguistic structure that is encoded in the hidden activations of the learned representations. Crucially, we perform a controlled comparison between the grounded **VISUAL** and the distributional **TEXTUAL** pathway: both models have the same architecture and share word-embeddings. As the linguistic interpretation of representations learned by recurrent networks did not enjoy a large amount of attention at the time we introduced two novel techniques.

Firstly, we introduced the *omission score*, an input perturbation based saliency metric assigning a real-valued importance score to each input token signaling how much impact did it have on the final sentence representation. Through computing the log ratios of the omission score distribution over part-of-speech and dependency labels between **VISUAL** and **TEXTUAL** we find that the former pays more attention to categories usually filled with semantically contentful words, while the attention distribution of **TEXTUAL** is fairly uniform.

To disintangle word forms from their functions we fit ridge regression models to predict omission scores for tokens using the word identity as predictor and adding dependency relation (`+dep`) or sentence position variables or both and their interactions. We find that the word-identity is much less predictive of omission score for

TEXTUAL than it is for **VISUAL** and that position is most informative for **TEXTUAL**, while for **VISUAL** dependency relation and position variables provide similar increases in R^2 . In a more fine-grained analysis we examined the omission distributions computed for the **VISUAL** pathway of words for which the increase in R^2 from the word-identity regression model to the **+dep** model is the highest. We find a general pattern that words generally produce the highest omission scores when they fill the noun subject or root function in a sentence and smallest when they appear as conjuncts.

Lastly we turn to contrasting what the individual dimensions of the two pathways encode. To do so we compute the mutual information between the binned activation values and different type of contexts. For these contexts we consider word and dependency relation n-grams up to order three. This results in distributions of mutual information values between activations and contexts. We take the median of these distributions to compare the types of contexts that are more related to the activation patters in **VISUAL** than **TEXTUAL**. We find the significant difference between the pathways that features encoded by **TEXTUAL** are more related to dependency labels while that of **VISUAL** are more related to words. We can also use these mutual informatiton scores to find for each dimension of the hidden states of the recurrent networks, which contexts they are most related to. On visual inspection we find that for both **VISUAL** and **TEXTUAL** that these contexts tend to be a combination of semantic/syntactic constructions. Consider for example two of these top contexts for one of the hidden units of **TEXTUAL**: *male on a*, *person rides a*. For **VISUAL** we find contexts to be more topically than syntactically related, however.

Through the development and application of the omission score and mutual information based interpretation techniques we have found similarities and differences between the sentence representations learned by a image–sentence ranking model and a language model.

Since our work, however, there have been a large number input token saliency measures introduced as discussed in Section 2.7. Shrikumar et al. (2017) points out that perturbation based techniques struggle due to the limited perturbation window i.e.: the important context might be larger than the scope of the perturbation function. On the explanation evaluation benchmark experiments of Poerner et al. (2018b) perturbation based methods (including ours) lead to inconsistent results and backpropagation style methods (Bach et al., 2015; Shrikumar et al., 2017) have a stronger performance in general.

To find typical inputs to hidden units Poerner et al. (2018a) develops an alternative to our mutual information based approach and applies it to our IMAGINET architecture. They perform gradient ascent on maximizing the activation values for particular dimensions. Their results reproduce our findings that the hidden units of TEXTUAL tend to be more syntax aware than that of VISUAL.

Interpretation of deep models of language have become a sub-field of NLP in its’ own right with dedicated venues such as the BlackboxNLP Workshop at EMNLP 2018 (?). Future work in the field linguistic representation learning can benefit from these analysis methods by shedding more light onto the differences between learning from different cues such as the linguistic versus perceptual contexts we considered in this thesis.

Improving translation with visual grounding

Multimodal machine translation has been introduced as a shared task (Specia et al., 2016c) in the First Conference of Machine Translation (WMT16) initially with German and English (Elliott et al., 2016b) later with added French and Czech data (Elliott et al., 2017b). The task is machine translation with added side information in the form of images. Through a review of the state-of-the-art we observe in Chapter 5 that the multi-modal and text-only versions of the top performing systems during the first competition have very similar performances (?). Furthermore, when systems do perform better it is unclear if they successfully use images as context to aid translation or they learn better representations through visual grounding.

In Chapter 5 rather than conditioning translation on the additional image context we introduce an architecture to learn visually grounded representations jointly with translation. More precisely we train a shared encoder which provides input representation to an image–sentence ranking and a attentional translation decoder. The two sub-models are trained jointly with multi-task learning, much like **IMAGINET** in Chrupała et al. (2015a).

We considered two setups: 1.) *aligned* setting where the input is triplets composed of an English sentence, its German translation and a corresponding image, 2.) *disjoint* where we have a separate English-German parallel corpus and an image–sentence corpus in English. We find no significant difference in performance between the *aligned* and *disjoint* settings. This result provides evidence that visual grounding can provide a useful inductive bias to improve translation quality.

We also performed a follow up experiment where we improved

our text-only baseline with training on an additional English-German parallel corpus. We observed that even when extra translation data is available visual grounding still provided improvements in performance. Finally, our full system with the extra parallel corpus and an additional image–sentence data set achieved 2nd place according the human judgements in the WMT Shared Task on Multimodal Translation and Multilingual Image Description (Elliott et al., 2017b) on the unconstrained task out of 16 submissions.

On this Shared Task for some systems the multi-modal variant achieves better performance (Caglayan et al., 2017), while the text-only is better for others (Ma et al., 2017). The results of the third shared task are in line with the previous years: adding images as extra context to translation systems result in marginal differences in translation quality (Barrault et al., 2018). Elliott (2018) investigate the issue further and introduces a measure of the image awareness of multi-modal translation models and conclude that the current version of the Multi30K data set probably does not contain many training samples where the models need to take the visual modality into account for translation. The role of visual context in translation remains an active area of research at the time of writing this thesis: the "Best Short Paper" title at the North American Chapter of Association for Computational Linguistics 2019 was awarded to (Caglayan et al., 2019) who show that multi-modal systems are insensitive to images in general , however, the visual contexts can help models recover from corruptions to the source sentences.

Multilingual visually grounded sentence representations

We show in Chapter ?? that visually grounded sentence representation learning provides a useful inductive bias for machine translation. Kiros et al. (2018) also report improved translation performance on the English–German and English–French Multi30K and IWSLT 2014 German–English (Cettolo et al., 2014) translation tasks, when initializing the translation models with their grounded Picturebook word-embeddings. They also show that combining pre-trained GloVe (Pennington et al., 2014) and Picturebook embeddings lead to improvements on natural language inference on the SNLI (Bowman et al., 2015) and MultiNLI Williams et al. (2017b) data sets and on predicting semantic relatedness on the SICK data set (Marelli et al., 2014a). (Kiela et al., 2017) through transfer experiments on entailment and sentence classification tasks find that the representations learned an image–sentence ranking model train on COCO – similar to the ones trained in Chapters 5, 6, ?? – outperform that of their SkipThought (Kiros et al., 2015) implementation. They conclude that visual grounding leads to qualitatively different representations, which can be beneficial many tasks.

Given the promising results on the benefit of visual grounding on sentence level tasks it seems to be an important avenue to explore techniques to learn better quality and more general multi-modal representations. To this end in Chapters 6 and ?? we turned to learning grounded representations for multiple languages jointly. The benefit of multilingual joint learning have been demonstrated for example in dependency parsing (Ammar et al., 2016), machine translation

(Johnson et al., 2016) and grapheme-to-phoneme conversion (Peters et al., 2017). In the visually grounded representation learning (Gella et al., 2017) showed improved performance in some cases for image–sentence ranking and semantic textual similarity when training on two languages jointly.

In Chapter 6 we improve and expand the results of Gella et al. (2017). Firstly, contrary to their results we report consistent performance gains in the bilingual setting in our setup: bilingual joint training improves for on both English and German image–sentence ranking experiments and the cross-lingual caption–caption ranking objective provides further benefits in both cases. Furthermore, we show that the results of the bilingual model can be improved by training with two additional langauges: French and Czech.
